Contributor Biographies

Kiki Adams is a Computational Linguist and Data Scientist who specializes in psychology and natural language processing. Kiki is Head of Science at Receptiviti, where her team discovers and develops innovative ways to use language in modelling cognition, emotion, personality, and behavioral patterns to solve diverse business problems.

Audrey E. Aday, BA, is a graduate student in social/personality psychology at the University of British Columbia.

Jonathan M. Adler is an associate professor of psychology at Olin College of Engineering. He is also an associate editor of *Journal of Personality*, visiting associate professor of medicine at Harvard Medical School, and chief academic officer of the Health Story Collaborative. His research focuses on narrative identity development and its association with psychological well-being. Currently, his research examines embodied aspects of identity, including the life narratives of people with disabilities.

Sara G. Alves (Master's student, University of Porto) is a student of psychology, specializing in the area of social, organizational, and work psychology, in the Faculty of Psychology and Educational Sciences of the University of Porto. Her research interests include political psychology and group processes, as well as the development and elimination of prejudice. Currently she is working on a paper about social representations of sport by disabled athletes and is aiming to continue in postgraduate education.

Michael C. Ashton is a professor of psychology at Brock University in St. Catharines, Ontario, Canada. He received his PhD from the University of Western Ontario. He is the author of the textbook *Individual Differences and Personality* and co-author (with Kibeom Lee) of *The H Factor of Personality*.

Sarah E. Babcock is a PhD candidate at the University of Western Ontario in the social-personality and developmental psychology area. Her research interests include individual differences, cognitive ability assessment, scale development, and student resilience. Her recent publications include C. A. Wilson, S. E. Babcock, & D. H., Saklofske (2019) "Sinking or swimming in an academic pool: A study of resiliency and student success in first-year undergraduates" (*Journal of Higher Education*), S. E. Babcock et al., (2018) "WISC-V Canadian norms: Relevance and use in the assessment of Canadian children" (*Canadian*

Journal of Behavioural Science) and S. E. Babcock et al. (2017) "Test review: School motivation and learning strategies inventory (SMALSI): College form" (*Canadian Journal of School Psychology*). She previously worked for Pearson Clinical Assessment as project coordinator for Canadian adaptations of intelligence and behavioral assessment tools.

Anjana Balakrishnan (MSc in Psychology-Personality and Measurement, the University of Western Ontario, 2015) completed her PhD in Social Psychology with a specialization in Migration and Ethnic Relations at the University of Western Ontario. Anjana is a member of the Canadian Psychological Association and a member of the Society for Personality and Social Psychology. Her research interests lie in the study of student success, international students, immigration, prejudice, how personality and culture interact to exert influence in life domains, and intercultural and interethnic relations.

Sanna Balsari-Palsule has a PhD from the Department of Psychology at the University of Cambridge. Her research interests include examining the dynamics of personality in organizations, such as the benefits and costs of enacting extraversion in the workplace on well-being and performance outcomes.

Rachele Benjamin is a PhD student in social/personality psychology at the University of British Columbia. She is a member of the Culture and Self lab. Her research focuses on responses to threat and perceived meaninglessness, as well as the processing of uncertainty across cultures.

Aaron Bermond is a PhD student at the University of Southern Mississippi. His current research interests lie in understanding the underlying factors that motivate media use and attachment.

Navjot Bhullar, PhD, is an associate professor of psychology at the University of New England, Australia. Her research focuses on examining a range of psychological, emotional, and environmental factors influencing mental health and well-being.

Julia K. Boehm is an assistant professor of psychology at Chapman University. She received her PhD in psychology from the University of California, Riverside and was a postdoctoral fellow at Harvard School of Public Health. Dr. Boehm's research centers broadly on well-being and investigates how people can thrive both mentally and physically. Specifically, her research examines whether psychological characteristics such as optimism and life satisfaction are associated with improved cardiovascular health. She is also interested in the behavioral and biological processes that are relevant for cardiovascular health. She has authored an extensive review in *Psychological Bulletin* on these topics.

Ryan L. Boyd is an assistant professor of behavioral analytics at Lancaster University in the United Kingdom. Dr. Boyd's research spans the areas of language analysis, personality processes, motivation and emotion, and assessment methods. His recent work has primarily focused on using language analysis paired with machine learning and big data techniques to explore motivational processes in domains such as forensic psychology and social/personality psychology. He is the co-creator of several text analysis programs and paradigms, including the Meaning Extraction Helper and LIWC2015.

Jacek Buczny is an assistant professor in the Department of Experimental and Applied Psychology at Vrije Universiteit Amsterdam. His research interests include studying implicit and explicit mechanisms of self-regulation, short- and long-term improvement in self-control, and the relationship between self-control and behavioral addictions (gambling, workaholism). Recent, noteworthy publication: M. Muraven, J. Buczny, and K. F. Law (2019). "Ego depletion: Theory and evidence." In R. M. Ryan (Ed.), *The Oxford Handbook of Human Motivation*. (2nd ed., pp. 113–134). Oxford: Oxford University Press.

Marie Buda (PhD, University of Cambridge, 2013) received her doctorate in cognitive neuroscience from the University of Cambridge. She was formally Bye-Fellow and college lecturer, as well as director of studies in psychological and behavioral sciences at Downing College, University of Cambridge. During her time there, she was shortlisted for the Student Union's Teaching Award. She is currently a behavioral science consultant at Innovia Technology.

Celine Cammarata received her BA in psychology and neuroscience from the Macaulay Honors College at Hunter College, City University of New York, in 2012. She is now pursuing a PhD in Cornell University's Human Neuroscience Institute, where she investigates brain-body connections and their influence on cognition.

Jennifer E. Caplan is a doctoral candidate at Widener University's Institute for Graduate Clinical Psychology. She is completing concentrations in psychoanalytic psychology as well as child, adolescent, and family therapy. Her clinical and research interests include early childhood dissociation and developmental trauma.

Bernardo J. Carducci, PhD, was professor emeritus of psychology and Director of the Shyness Research Institute (www.ius.edu/shyness) at Indiana University Southeast and a Fellow of the American Psychological Association in Divisions 1: General Psychology, 2: Teaching of Psychology, 8: Personality and Social Psychology, and 52: International Psychology. He is the author of *The Psychology of Personality: Viewpoints, Research, and Applications* (3rd ed., 2015, Wiley) and *Shyness: A Bold New Approach* (2000, HarperCollins) and other books related to shyness translated into multiple foreign languages.

Jonathan M. Cheek is a professor of psychology at Wellesley College. His graduate study mentors were Arnold Buss, the University of Texas, Austin (MA), and Robert Hogan, Johns Hopkins University (PhD). He studies identity orientations, narcissism, shyness, and introversion, and is interested in the development and evaluation of personality scales.

Nathan N. Cheek is a PhD student in psychology at Princeton University. He studies how people understand the self and others, the consequences of having too much choice, stereotypes about poverty, and other topics at the intersection of social cognition and judgment and decision-making.

Douglas E. Colman received an MBA from Adams State University, and a PhD in experimental psychology from Idaho State University, and is an assistant professor at the University of Wisconsin–La Crosse. His research interests include personality and interpersonal perception, especially when applied to industrial and organizational issues. He is the primary author of "Seeing and feeling your way to accurate personality judgments:

The moderating role of perceiver empathic tendencies" (2017), *Social Psychological and Personality Science* and recently wrote a handbook chapter titled "Characteristics of the judge that are related to accuracy" (in press) for the *Oxford Handbook of Accurate Personality Judgment*.

Keith S. Cox is an assistant professor of psychology at UNC Asheville. He is a clinical and personality psychologist. His research focuses on how memory for emotionally intense experiences relates to identity, emotional well-being, and clinical dysfunction. In the context of personality, he researches how life-story high and low points are associated with and predict subjective well-being and emotional health. In the context of PTSD, he researches how trauma memories change through the course of treatment.

Phebe Cramer (PhD clinical psychology, New York University, 1962) is professor emerita, psychology, at Williams College, and a fellow of the Society for Personality Assessment. She has been an associate editor for the *Journal of Personality*, and the *Journal of Research in Personality*. Her areas of research include defense mechanisms, narcissism, identity, and longitudinal development. She is the author of *The Development of Defense Mechanisms: Theory, Research and Assessment* (1991); *Protecting the Self: Defense Mechanisms in Action* (2006); *Story-telling, Narrative and the Thematic Apperception Test* (1996); and *Word Association* (1968).

Andreana Dingess is an undergraduate student majoring in psychology at Case Western Reserve University. She is a research assistant in Julie Exline's laboratory. Her research is concerned with the psychology of religion and spirituality, specifically focused on religious and spiritual struggles in life-story episodes.

Corey F. Doremus is a graduate student in Rowan University's clinical psychology PhD program. He holds an MA in psychology from Rutgers University–Camden. His research interests include the role of alcohol in sexual violence perpetration and victimization.

William L. Dunlop is an assistant professor of personality psychology at the University of California, Riverside. He examines personality, self, and identity using both idiographic and nomothetic approaches.

Grant W. Edmonds is a research scientist at the Oregon Research Institute. Dr. Edmonds received his BA from St. John's College in philosophy and the history of mathematics, and his PhD in personality psychology from the University of Illinois at Urbana-Champaign. He primarily works on the Hawaii Personality and Health Study, an ongoing longitudinal study initiated in 1959. His work integrates personality development across the lifespan into models of physical and cognitive health. This work is motivated by research linking personality to mortality, and involves identifying pathways linking personality to objective biomarkers and health outcomes over long spans of time.

S. B. G. Eysenck (retired) is affiliated with the Psychology Department at the Institute of Psychiatry. Most of her interests and subsequent work was influenced by her marriage and work partnership with Professor H. J. Eysenck with whom she had four children. However, her main work interests also included research in personality psychology specifically in the questionnaire measurement of the dimensions of personality and cross-cultural research of the basic dimensions of personality (Barrett, Petrides, S. B. G. Eysenck, & H. J. Eysenck,

1998). Impulsiveness and venturesomeness (S. B. G. Eysenck, 2004) also became part of her program of research, as did addiction vulnerability, criminality, junior versions of all questionnaires, and cross-cultural studies associated with these areas of research.

Michael G. Feeney is a recent graduate of Rutgers University, having earned a BA in both psychology and philosophy. His research interests include personality research methodology and philosophy of psychology.

Nicole D. Ferris (MA, Rutgers University, 2019) is a recent graduate of the psychology program at Rutgers University–Camden. Her research interests include learning, working memory capacity and academic achievement.

Sara Fiorot is a graduate student pursuing a Master's degree in psychology at Rutgers University–Camden. She has previously earned Master's degrees in philosophy and sociology. Her current research involves person perception and self-presentation. Specifically, she is examining behaviors associated with making, and perceiving that one has made, a desirable impression on others. Other areas of interest are happiness and well-being and cultural psychology.

Gili Freedman is an assistant professor at St. Mary's College of Maryland. Her PhD is in social and personality psychology, and her research focuses on two themes: the two-sided nature of social rejection and gender biases against women in STEM fields.

Lewis R. Goldberg is a senior scientist at the Oregon Research Institute and an Emeritus Professor of Psychology at the University of Oregon. Among his honors are the Jack Block Award for outstanding career contributions to personality research from the Society of Personality and Social Psychology, the Saul Sells Award for outstanding career contributions to multivariate research from the Society of Multivariate Experimental Psychology, and the Bruno Klopfer Award for outstanding lifetime contributions to personality assessment from the Society of Personality Assessment. His contributions to the scientific literature in personality and psychological assessment have included articles on judgment and decision-making, and the development of taxonomies of personality-descriptive terms in diverse languages. To provide public-domain measures of the most important personality attributes, he has developed an Internet-based scientific collaboratory, the International Personality Item Pool (IPIP: http://ipip.ori.org/).

William G. Graziano, PhD, is a professor in the Department of Psychological Sciences, Purdue University, in West Lafayette, Indiana. He earned his PhD in psychology at the University of Minnesota. His interests are in motivational processes and behavior. For approximately 30 years, he and his research team and his collaborators focused on the motivational foundations for individual differences in agreeableness.

Jeff Greenberg is a professor of psychology at the University of Arizona. He co-developed terror management theory, which explains how awareness of mortality influences many aspects of human behavior. His research focuses on prejudice, self-esteem, political preferences, aggression, aging, religion, attitudes toward animals, and existential isolation. His recent co-authored books include: *Death in Classic and Contemporary Film: Fade to Black* (2013), *The Worm at the Core* (2015), *Social Psychology: The Science of Everyday Life* (2015).

Yael Gross completed her MA in psychology at Rutgers University–Camden and is currently a doctoral student in School Psychology at Lehigh University. Her research interests focus on evaluating the coordination between the family, school, and medical systems for children with chronic health conditions.

Kate Guan is a Master's student studying social/personality psychology at the University of British Columbia. She is a member of the Culture and Self lab studying cross-cultural differences in romantic relationships, and how romantic partners provide meaning to individuals living in different cultural contexts.

Sarah E. Hampson, PhD, is a senior scientist at the Oregon Research Institute. She studies personality and health over the lifespan. Originally from the UK, she held academic appointments at the University of Lancaster, Birkbeck, University of London, and the University of Surrey before moving to Oregon. She is a past president of the European Association of Personality Psychology. In her research, she examines the influence of personality traits on health behaviors and health status at various stages of the life course from infancy to old age.

Peter J. Helm, PhD, is a postdoctoral fellow at the University of Missouri working under the mentorship of Jamie Arndt. His research focuses on existential isolation, self-esteem, aggression, self-presentation, meaning, and attachment.

Patrick L. Hill is an assistant professor of psychological and brain sciences at Washington University in St. Louis. Dr. Hill received his BA from Indiana University in psychology and economics, and his MA and PhD in cognitive psychology from the University of Notre Dame. His research examines the mechanisms underlying personality trait change, as well as on how personality traits predict health and well-being outcomes across the lifespan, with a primary focus on dispositional characteristics such as conscientiousness and sense of purpose.

Jill A. Jacobson (PhD, Ohio State University, 1999) is an associate professor of psychology at Queen's University, Canada. Her research interests broadly fall within the area of motivated social cognition primarily examining the effects of two personality constructs, causal uncertainty, and dysphoria. More recently, she has been investigating various aspects of the self including the effects of religion on self-control and individual differences in the importance placed on having high self-esteem. She has received research funding from the Social Science and Humanities Research Council, the Canadian Foundation for Innovation, and the Ontario Problem Gambling Research Centre.

James Kean is research fellow at Monash Institute of Cognitive and Clinical Neurosciences (MICCN) and leads a team of researchers investigating all aspects of attention in children (aged 3 to 6). He is also an associate investigator at the Centre for Human Psychopharmacology, directed by Professor Con Stough, at Swinburne University of Technology since 2014. He earned a Bachelor of Science in Psychology in 2008 at Deakin University, Melbourne, and an Honors Degree in Psychophysiology in 2009, at Swinburne University of Technology. He is currently earning a doctorate in Science (Neuropharmacology), with a specific focus on child and adolescent neuroscience and complementary alternative medicine research. His work has been published in a number

of international journals including *Psychopharmacology, Frontiers in Pharmacology, Phytotherapy Research, Complementary Therapies in Medicine, Nutrients, Nutrition Journal,* and *Journal of Alternative and Complementary Medicine*.

Lucas A. Keefer (PhD, Kansas, 2014) is an assistant professor at the University of Southern Mississippi. His research interests include attachment, existential, and political psychology.

Margaret L. Kern is an associate professor at the Centre for Positive Psychology at the University of Melbourne's Graduate School of Education. Originally trained in social, personality, and developmental psychology, Dr. Kern received her undergraduate degree in psychology from Arizona State University, a Masters and PhD in social/personality psychology from the University of California, Riverside, and postdoctoral training at the University of Pennsylvania. Her research is collaborative in nature, and draws on a variety of methodologies and interdisciplinary perspectives to examine questions around who flourishes in life, why, and what enhances or hinders healthy life trajectories.

Sheherezade L. Krzyzaniak, MS, is a PhD candidate of Experimental Psychology at Idaho State University. Her research interests include personality judgment accuracy and the ways in which accurate perceptions are formed, specifically characteristics of the judge and target that influence components of accuracy. She has first-authored "The effect of information quantity on the distinctive accuracy and normativity of personality trait judgments" (2019), *European Journal of Personality*. Her work has also included development of resources for educators, including a chapter in the *Oxford Handbook of Accurate Personality Judgment*.

Timothy J. Kutta, PhD, is a postdoctoral researcher at the Autism Institute in the College of Medicine at Florida State University. He is an expert in quantitative methods, has published on the cognitive psychology of language and learning, and currently focuses on establishing the best diagnostic tools for early detection of Autism Spectrum Disorder.

Kristin Layous has a PhD in social and personality psychology from University of California, Riverside and is currently an assistant professor of psychology at California State University, East Bay. Her research primarily focuses on activities that promote happiness like expressing gratitude and performing kind acts. Specifically, she explores how and under what conditions these activities boost happiness and who they are most likely to help.

Kibeom Lee received his PhD in I/O psychology from the University of Western Ontario in 2000. He is currently a professor in the Department of Psychology at the University of Calgary. He was previously faculty member in the Department of Psychology in the University of Western Australia, Perth, Australia. His research interests include personality structure/measurement and pro- and anti-social behaviors at work.

Tera D. Letzring is a professor of psychology and the Director of the Experimental Psychology PhD program at Idaho State University, and an associate editor for the *Journal of Research in Personality*. Her research focuses on the accuracy of personality judgments, and in particular on moderators of accuracy. She is a co-editor of *the Oxford Handbook of Accurate Personality Judgment*, and has published articles in several journals, including

the *Journal of Research in Personality*, the *European Journal of Personality*, and *Social Psychological and Personality Science*.

Uri Lifshin, PhD, is a postdoctoral fellow at the Interdisciplinary Center in Herzliya, Israel working under the mentorship of Mario Mikulincer and Gilad Hirschberger. His research interests include: terror management theory, motivation, self-esteem, aggression, religion, prejudice, and the human-animal relationship.

Brian Little is a research professor at Cambridge University and lectures in the Department of Psychology and the Cambridge Judge Business School. He is also distinguished research professor emeritus at Carleton University in Ottawa and senior fellow at Wharton Person Analytics, University of Pennsylvania. He initiated the study of personal projects and has published widely on personality, social ecology, and project pursuit, especially in terms of human flourishing. He co-edited *Personal Project Pursuit: Goals, Action and Human Flourishing* in 2007. In 2014 he published *Me, Myself and Us: The Science of Personality and the Art of Well-Being* and in 2017 *Who Are You, Really?*

Elizabeth A. Mahar is a PhD student in the social psychology program at the University of Florida. She received her MS in psychology at Villanova University. Her research focuses on sexual and romantic relationships.

Heather M. Maranges is a doctoral candidate in social psychology at Florida State University. She is interested in understanding the psychological processes underpinning cooperation and prosociality. Accordingly, Heather studies individual differences (i.e. self-control), social and moral cognition, and their intersection, complementing traditional social and individual difference methods with those of cognitive psychology, neuroscience, and genetics. To sample her work, Baumeister, Maranges, & Vohs (2017).

William D. Marelich, PhD, is professor of psychology at California State University, Fullerton, and consulting statistician for Health Risk Reduction Projects, Integrative Substance Abuse Programs (ISAP), Department of Psychiatry and Biobehavioral Sciences, David Geffen School of Medicine at University of California, Los Angeles (UCLA). His research interests and publications address decision-making strategies in health settings, patient/provider interactions, HIV/AIDS, and statistical/methodological approaches in experimental and applied research. He is co-author of the book *The Social Psychology of Health: Essays and Readings*, and is an editorial board member of the *International Journal of Adolescence and Youth*.

Patrick M. Markey, PhD, is a professor of psychology, the director of the Interpersonal Research Laboratory at Villanova University, and a former president of the Society for Interpersonal Theory and Research. His research has been presented in over 100 journal articles, conference presentations, and book chapters. Much of this research has received considerable attention from television, radio, and print media, including *The New York Times*, *USA Today*, NPR, CBS, MSNBC, the BBC, ABC, and many others.

Frank Martela is currently a postdoctoral researcher at Aalto University, Finland. His main research focus is on self-determination theory, meaning in life, compassion, prosocial

behavior, and well-being. He received his PhD in applied philosophy and organizational research from Aalto University, Finland in 2012. His interdisciplinary work covers personality and social psychology, organizational research, as well as philosophy, and he has published in journals such as the *Journal of Personality*, *Journal of Positive Psychology*, *Journal of Happiness Studies*, *Organization Studies, and Metaphilosophy*.

Kira O. McCabe is a postdoctoral research fellow at Vanderbilt University working on the Study of Mathematically Precocious Youth (SMPY). Her work explores the relations of context-specific goal pursuit to personality states, as well as achievement motivation, and personality development. Her work has been published in *Psychological Science* and the *Journal of Personality and Social Psychology* among other publications.

Amelia Munson is a PhD student in the Animal Behavior Graduate Group at the University of California at Davis, currently advised by Dr. Andrew Sih. She recently returned from a summer at Monash University in the lab of Dr. Bob Wong where she was funded by an NSF EAPSI fellowship. Her research interests include how early life experience, cognition, and social behavior contribute to variation in response to novel environments.

Theresa Murzyn, PhD is a user experience researcher and part-time lecturer for the psychology department at Rutgers University–Camden, New Jersey. Her research interests include rejection, rejection sensitivity, personality development, personality stability and change, self-esteem, and persuasion.

Autumn D. Nanassy graduated from Rutgers University–Camden with her Master's in Psychology in 2016. She is currently a Trauma Research Coordinator focusing on pediatric trauma and burns at St. Christopher's Hospital for Children in Philadelphia and lectures part time at Rutgers University–Camden.

Shana M. Needham completed her BA at Oregon State University in anthropology and psychology. She also completed her MA at Oregon State in interdisciplinary studies. She recently completed her PhD in social-personality psychology at Queen's University, Canada. Her primary research interests are in the area of romantic relationships including not being in one (i.e. the fear of being single). For her dissertation, she examined the impact of causal uncertainty on conflict within romantic relationships.

Austin Lee Nichols, PhD, is the director of research at the Connection Lab and Adjunct Professor at the University of Navarra. His research interests include examining personality as a tool for predicting various phenomena, including leadership, social behavior, and driving. He also publishes regularly on the measurement of personality, with particular attention to the ability to measure constructs with fewer items.

Karen Nolidin is a researcher at the Centre for Human Psychopharmacology at Swinburne University. Her research interests include cognitive performance and aging in healthy older adults and interventions for maintaining and improving cognition in older age. She has co-authored several publications related to these topics.

Karynna Okabe-Miyamoto is a graduate student at the University of California, Riverside working with Dr. Sonja Lyubomirsky. She previously received her MA from San Francisco

State University and her BA from Chapman University, where she worked with Dr. Julia Boehm. Her recent work examines how connection in relationships (in-person or online, strong or weak ties) facilitates happiness, especially how social connection may be a key component in the effectiveness of positive activity interventions.

Anthony D. Ong is professor of human development at Cornell University. His research includes studies of resilience and lifespan development with specific interest in developmental plasticity or the capacity of individuals to flexibly adapt to changing environmental demands with age. A major focus of this work involves understanding the biobehavioral and socio-cultural pathways through which positive emotions contribute to health and well-being. He is the co-editor the American Psychological Association volume, *Emotion, Aging, and Health* (Bronfenbrenner Series on the Ecology of Human Development), as well as the *Oxford Handbook of Methods in Positive Psychology*.

Victoria L. Pace, PhD, is an associate lecturer and director of the MS program in industrial/organizational psychology at the University of Central Florida. She researches personality in the workplace, including development and validation of measures, administration of tests, and use of results for prediction of performance as well as for developmental purposes.

Brooke Piercy, BA, is a graduate student in psychology at California State University, Fullerton. Her research interests include health and social psychology, stress management, nutrition outreach, and statistical methods in applied research. Her current research focuses on the influences of diet and socialization on anxiety and stress.

Lea Pollack is a PhD student in the Ecology Graduate Group at the University of California at Davis, currently advised by Dr. Andrew Sih. She is an NSF Graduate Student Fellow. Her research interests include variation in behavioral responses to environmental change, urban ecology, and how the personality composition of social groups influences collective behavior.

Thomas J. Preston is a postbaccalaureate research assistant working in the Anxiety and Behavioral Health Clinic, directed by Dr. Norman Schmidt. His interests include elucidating the influence of risk factors for anxiety on various psychopathologies, such as posttraumatic stress disorder (PTSD) and substance use disorders (SUDS). He hopes to pursue a PhD in clinical psychology.

William Revelle is a professor of psychology at Northwestern University. His research includes developing open source measures of intelligence (Condon and Revelle, 2014), novel ways of measuring personality and ability using the web (Revelle et al., 2016), and methodological advances in the measurement of reliability (Revelle and Condon, 2018; Revelle and Zinbarg, 2009). He is the developer of the psych package for the open source statistical system, R, which is widely used in personality research. His theoretical work attempts to integrate models of within and between individual differences using formal models of dynamical processes (Revelle and Condon, 2015).

Tania A. Reynolds, PhD, is a postdoctoral researcher at the Kinsey Institute at Indiana University. Her program of research investigates social competition from an evolutionary perspective. She examined the evolutionary function of human grief (Reynolds, Winegard,

Baumeister, & Maner, 2015) and men's anti-gay bias (Winegard, Reynolds, Baumeister, & Plan, 2016). She received the NSF graduate fellowship to study the hormonal underpinnings of women's relationship insecurities (Reynolds, Makhanova, McNulty, Eckel, Nikonova, & Maner, 2018). She explores how women compete for mates by strategically disseminating peers' social information (Reynolds, Baumeister, & Maner, 2018) and how pressures to attract and maintain romantic relationships exacerbate women's dieting motivations (Reynolds & Meltzer, 2017).

Angela M. Sabates (PhD, Northwestern University, 1989) is an associate professor of psychology at Bethel University in St. Paul, Minnesota. She is a member of the Society for Personality and Social Psychology and the Christian Association of Psychological Studies. She is also a member and reviewer for the *American Scientific Affiliation*. Her research interests include perceptions of gender and aggression, multi-disciplinary understandings of psychology, and the implications of the liberal arts for designing undergraduate psychology curriculum. She authored and is currently working on the second edition of *Social Psychology in Christian Perspective: Exploring the Human Condition* (2012, InterVarsity Press).

Gerard Saucier (PhD, University of Oregon, 1991) is a full professor of psychology at the University of Oregon, and a senior research scientist at Oregon Research Institute. His research examines the structure and measurement of personality, worldview, values, and moral viewpoints, with strong attention to cultural factors and differences. He is the author of over 80 scientific contributions, mostly research articles, including recent work on the relative cross-cultural ubiquity of personality-attribute concepts, how personality varies across situations, frameworks for attitude measurement based on "ism" concepts from language, and which psychological variables are associated with the largest cross-cultural differences.

Nicola S. Schutte, PhD, is an associate professor of psychology at the University of New England, Australia. Her research interests lie in the area of positive psychology and include a focus on motivation, emotional intelligence, self-efficacy, and positive affect.

Andrew Sih (PhD, University of California, Santa Barbara, 1980) is a distinguished professor in the Department of Environmental Science and Policy, and chair of the Animal Behavior Graduate Group at the University of California at Davis. He is an ISI Highly Cited researcher, and a fellow, former president, and winner of the Quest Award and Exemplar Award from the Animal Behavior Society. His research interests include the study of predator-prey behavior and ecology, mating behavior and sexual selection, impacts of behavior multi-species interactions, behavioral responses to human-induced rapid environmental change, and how all these can be influenced by individual differences in personality.

Rúben L. Silva (Master's student, University of Porto) is a student of social, organizational, and work psychology in the Faculty of Psychology and Educational Sciences of the University of Porto. With research interests on political and social psychology, he is currently working on papers regarding attitudes toward refugees, regarding the social representations of sport by disabled athletes, and voting behavior in European elections, among others.

David J. Sparkman is currently an assistant professor of psychology at the University of Wisconsin–Eau Claire, and received his PhD in experimental psychology from the

University of Arkansas. His research primarily focuses on prejudice and intergroup relations, in which he examines the impact of multicultural experiences, intergroup contact, perspective taking, and diversity ideologies on various psychological outcomes (e.g. prejudice, political ideology, social cognition, motivation, personality). David is the first author of a paper published in the *European Journal of Social Psychology*, entitled "Multicultural experiences reduce prejudice through personality shifts in openness to experience."

Benjaman To (MB BChir, University of Cambridge, 2019) is a junior doctor who studied Medicine at Christ's College, University of Cambridge. His research interests include functional neurological disorder and clinical frailty.

Renée M. Tobin, PhD, is professor and chair of the Psychological Studies in Education Department at Temple University in Philadelphia. She earned her Master's in social psychology and her doctorate in school psychology at Texas A&M University. Her research focuses broadly on personality and social development. Specifically, she is interested in individual differences as predictors of children's responsiveness to social-emotional interventions. Her work can be found in both applied and basic research outlets including *Best Practices in School Psychology*, *School Psychology Quarterly*, *Psychological Science*, and *Journal of Personality and Social Psychology*. She is also co-author of *DSM-5® Diagnosis in the Schools*.

Zahra Vahedi is a graduate student completing her doctoral studies at Ryerson University in the Media and Social Development Lab. Her research interests include investigating the social, psychological, and cognitive effects of information and communications technologies (ICTs).

Sarah M. Vanacore is a PhD student in Clinical Health Psychology at East Carolina University. She previously earned a master's degree in English from the University of Pennsylvania and a master's in psychology from Rutgers University–Camden. Her current research involves veteran and military servicemembers' physical and mental health, with an emphasis on trauma and coping.

Thomas I. Vaughan-Johnston completed his BA (Honors) at the University of Alberta and his Master of Science at Queen's University, Canada, both in psychology. He is now a doctoral student at Queen's University studying topics in social-personality psychology including attitudes and introspection, self-esteem, experiential avoidance, and mindfulness. He currently is developing several personality scales including one measuring beliefs about self-esteem's importance. Thomas also enjoys contributing to the field in additional ways such as maintaining a monthly academic blog (https://sites.google.com/site/thomasvaughanjohnston/), volunteering at science fairs, and submitting articles for an online magazine for young scientists (CurioCity).

Anna Vozna is a doctoral student in language and literacy education at the University of British Columbia.

Deanna L. Walker, MA, is a doctoral candidate in clinical science and psychopathology at Western University in London, Ontario, Canada. Her research interests include positive psychology and investigating individual difference factors associated with individual and relational well-being.

R. Shane Westfall is currently an assistant professor of psychology at Western Wyoming Community College. He received a PhD in experimental psychology from the University of Nevada, Las Vegas in 2018. His research interests include physical-attractiveness stereotypes, mate selection, and social perception.

Joshua Wilt is a postdoctoral fellow in the department of psychological sciences at Case Western Reserve University. His research is broadly concerned with investigating affective, behavioral, cognitive, and desire (ABCD) components that are relevant to personality structure and function. His current research examines ABCDs within the context of personality traits and life-story episodes.

Keri Ka-Yee Wong (PhD, University of Cambridge, 2015) received her doctorate in psychology from the University of Cambridge and was subsequently the Betty Behrens Research Fellow at Clare Hall in the University of Cambridge. She is currently an assistant professor of psychology at University of College London. Her research interests include early assessments of childhood paranoia and suspiciousness, antisocial and aggressive behaviors, schizophrenia-spectrum disorders, and cross-cultural comparative research. Her most recent publication is a review on the developmental aspects of childhood schizotypy and suspiciousness (Wong & Raine, 2018).

Barbara Wood Roberts, PhD, is an experimental psychologist. Her research interest is the use of structural equation modeling to quantify intercultural competence in a higher education setting. She is the co-author of "What is c factor, and where can I get it?" (2016), *The Inquisitive Mind*.

Lucinda Woodward, PhD, is an associate professor in clinical psychology at Indiana University Southeast. Her research is in personality with a particular focus on the Interpersonal Circumplex. She is active in the sustainability movement at IU Southeast and teaches courses in environmental psychology and other upper-level undergraduate subjects. Her publications range from the impact of interpersonal violence on PTSD symptoms in war affected and normal populations to human perceptions of hostility in black dog breeds.

Fang Zhang (PhD, Cornell University, 2001) is an associate professor of psychology at Assumption College, a private liberal arts college in Worcester, Massachusetts. Her research interests include adult attachment, recognition of facial expressions of emotions, and the role of culture in interpersonal relationships. She has published many articles in these areas. Her most recent work examines cultural differences in recognition of subtle facial expressions of emotions, and the relationships between perception of facial expressions of emotions and the female menstrual cycle and interpersonal closeness.

Gordon Allport

Michael G. Feeney

Rutgers, The State University of New Jersey

Gordon Willard Allport was an early developer of personality psychology, and is particularly known for his development of trait theory, which heavily influenced the way personality is studied today. Allport also made important contributions to social psychology, including the study of prejudice, and was involved in the debate surrounding the development of psychological research methodology. He also authored the first major book on personality psychology: *Personality: A Psychological Interpretation* (1937). In addition to his theoretical contributions to the field, Allport was also an accomplished teacher. As a professor at Harvard University, Allport taught one of the first courses focused on personality. Stanley Milgram, who would go on to become one of the most influential and well-known psychologists in American history, was one of Allport's students. Allport was also elected president of the American Psychological Association (APA) in 1939.

Consistently motivated by social beneficence, Allport sought to develop personality psychology and use its findings for the betterment of society. He also sought to preserve the uniqueness and the importance of the individual from the recent scientific movement of behaviorism, where people were reduced to averages and were subject solely to universal instinct and environmental pressures. Personality psychology maintained that people were not reducible to these universal and external factors, but maintained a certain level of individuality in their personality traits, which were the primary determinates of behavior. Although the current state of trait theories in personality differ significantly from Allport's original theory, he was primarily responsible for its initial development in American psychology.

Gordon Allport was born on November 11, 1897, in Montezuma, Indiana. His parents were Nellie Edith Allport and John Edwards Allport. Gordon Allport was the youngest of four boys. His older brother Floyd also became a psychologist. Before he was born, as well as after, Gordon Allport's family moved around the country a number of times. Gordon's father John became a medical doctor shortly before he was born. Allport's early school years were mostly spent in a suburb of Cleveland, Ohio. His family were practicing Methodists and his mother was especially devout, growing up in a strict, Free Methodist

household, and expressing desire that her sons enter into a religious vocation, such as missionary. Although eventually leaving the Methodist church for the Anglican-Episcopal church, throughout his life Allport continually affirmed his commitment as a religious man and wrote religious books during his lifetime (Nicholson, 2003).

Nellie Allport took on the primary responsibility of her children's spiritual development. Herself, growing up in an exceptionally devout Free Methodist household, Nellie instilled a great deal of religious ideals in her children. Prominent in these ideals were community engagement, hard work, and very little room for recreation. She was involved in many community organizations focused on goals such as female decorum and temperance. Allport's father John was not quite as involved in their religious education but was an important influence on his children's work ethic.

Allport's religious upbringing was steeped in ideals of hard work, selfless service, and the development of good character, not just in the self, but of society in general. This was during a time when an influx of immigration and increasing levels of urbanization were constantly changing the cultural tone in America, and decreasing its societal homogeneity. Thus, Allport's upbringing involved a sort of resistance to the perceived increasing focus of society on material wealth and worldly possessions. The family home itself served as a medical clinic, where Allport himself would contribute in various capacities as he grew older. Gordon's father was himself a hard-working country doctor, claiming to never have taken a vacation. After the move to Ohio, John Allport's accounts of Gordon's later time at Harvard suggested he very much kept to the strict, hard-working tradition instilled in him by his parents.

Upon graduating secondary school, Allport earned a scholarship to Harvard University. His brother Floyd was currently earning a PhD in psychology. Allport initially struggled academically, however, he eventually became more comfortable with the demands of college life and earned a bachelor's degree in both philosophy and economics. Allport's commitment to social service pushed him to heavy involvement with Harvard's department of social ethics. The department of social ethics was a somewhat new department at Harvard, which was focused broadly on using the insights gained from science to practice and further the ideals of social service. The department's mission became more crucial as the structure of society was changing and social work required more than just beneficent volunteers. The practice of using findings from the social sciences to determine the best course of action for a better society was of special interest to Allport, and he was able to witness the changing nature of social work in America. One of the important shifts in the philosophy of modern social work was a focus on the idiosyncrasies and nuances of individual cases. This was likely an important influence on Allport's development of personality and his emphasis on an idiographic approach to psychology.

Although Allport did not have an initially strong undergraduate focus on psychology, he would become intrigued by the subject after enrolling in Hugo Munsterberg's psychology class. Munsterberg himself was an impressive figure in the field of psychology, being at the time the senior professor in the Harvard psychology department. Allport did not particularly enjoy the class and did not like Munsterberg as an instructor, but the class did introduce him to the concept of exploring human nature using scientific exactitude. Munsterberg's predecessor, William James, would also have a great impact on Allport's philosophical development.

After graduating in 1919, Allport briefly taught in Constantinople, Turkey as part of a Methodist organization. His decision was likely motivated by his mother's early influence, which involved a large amount of enthusiasm for missionary ideals. Three of Allport's older brothers were in fact named after missionaries. However, despite this, Allport's family was somewhat displeased with his decision to move to Turkey, and convinced him to shorten his stay there. During this time, he developed his skill as a teacher, as well as experienced the relatively poor conditions in Turkey, which had a lasting impact on his philosophical outlook.

Allport's time in Turkey would not last long, however, and he soon followed in his brother's footsteps and returned to Harvard to pursue a PhD in psychology. On his way back to the United States he stopped in Vienna and met with Sigmund Freud. The encounter left Allport somewhat dissatisfied with psychoanalysis, but he claimed it was nonetheless an important influence on his later work on personality. Allport studied both psychology and social ethics in graduate school, but his main focus was psychology. Allport's interest in personality was also partially inspired by his brother's suggestion. It was a natural direction to take for Allport, being averse to the concept of instinct and the current dominance of behaviorism. The subject of his dissertation was the measurement of personality traits, and was in part a response to a recent call for individual assessment beyond simply intelligence testing. Specifically, Allport tested the traits ascendance-submission, which reflected a sort of dominance in social interactions, and introversion-extroversion. Allport's work on personality was motivated partially by a desire for practical benefit, and partially by a desire to preserve individuality in an increasingly depersonalized world, as well as a behaviorist and positivist scientific climate. Another motivation though was an attempt at standardizing the measurement and study of personality. Although Allport was not the only psychologist interested in personality, he was among the first to bring this sort of methodological order.

Following this, Allport would spend two years abroad on a traveling fellowship. He spent the first year in Germany, and the second at Cambridge, in England. Allport later stated that his time abroad had a significant impact on his intellectual development. He had a productive interaction with German psychologist William Stern, who was also interested in individual differences. He became particularly fond of the German philosophy regarding psychological research, with somewhat less focus on the detached quantification of research that was common in America. During his time in Germany, Allport also found great insight in reading works by William James. James provided Allport with the philosophical support to be able to balance his religious convictions with his desire for objective science.

After seizing the opportunity to renew his traveling fellowship for another year, Allport traveled to Cambridge. Allport's father died while he was at Cambridge, and the serene environment helped provide Allport with some comfort. Aside from that, Allport found little to gain academically from his time there. He was far less impacted by the state of psychological science in England. Allport would return to Harvard to teach, but as a part of the department of social ethics rather than psychology. He went initially to cover classes for his old mentor in the social ethics department, James Ford. Allport had some apprehensions about teaching, but accepted the offer on the hopes that he could teach a class of his own design, on personality.

It was during his time in teaching for the department of social ethics that Allport offered his first course on personality. Originally listed under "Personality and Social Amelioration," and

subsequently renamed "Personality: Its Psychological and Social Aspects," this course is widely credited as the first course offered on personality in America. As the original title suggests, this course, as a part of the department of social ethics, was not strictly a class on the psychological study of personality, but rather on personality within the context of social issues.

Allport desired to transfer to the department of psychology. However, this was not immediately possible, due to their faculties' desire to maintain psychology as a strictly experimental science. Allport's travels abroad had exposed him to a number of different influences that shaped his scientific philosophy and intellectual development, some of which were not aligned with the highly positivistic and quantitative expectations of American Academia. After two years teaching in the department of social ethics at Harvard, Allport briefly transferred to Dartmouth, but first he would marry Ada Lufkin Gould, a clinical psychologist and fellow Harvard graduate. The two had been romantically involved for several years, maintaining communication during Allport's time abroad. After two years at Dartmouth, Allport returned to Harvard as a professor of psychology, where he would remain for the rest of his career, and his eventual death in 1967.

It is difficult to consider Allport's impact on the field of psychology without considering the context in which personality psychology was developed. During the late nineteenth and early twentieth centuries, behaviorism and positivism were a strong force in psychology and in science in general. This meant that there was a methodological and theoretical push to treat psychology much like the natural sciences, which relied on assumptions of both homogeneity and malleability of humans. For behaviorists, human behavior was simply a function of past experience of situational responses to certain behaviors. The mechanism was the same for all people and there was no room for individual differences or the uniqueness of the person.

Sigmund Freud's psychoanalytic theory was also prevalent during this time, which similarly saw people as subject to unconscious processes that were largely a result of childhood experiences and sexual drives. For psychoanalysis, individuals were treated differently, but only in terms of differential childhood experience, and not any enduring individual qualities or motivations, like in Allport's trait theory. For Allport, assessing and predicting a person's behavior required measuring these individual qualities known as traits, and that these traits were determinative of behavior. That is, different people may behave differently in similar situations, precisely because they have different traits. For example, a person with the trait of shyness may not talk to many people at a party *because* they are shy. The trait is something internal, and part of their personality, not something simply learned through past experience.

Social and moral trends in society during Allport's time also highlight the significance of his work, and also may help explain some of it. During that time, there was a heavy emphasis on character development. At the time, character was a morally loaded term, and necessarily entailed certain socially desirable characteristics of the era, many of which were religiously motivated. Allport himself was highly motivated by societal beneficence and philanthropy. However, among other things, urbanization in America was playing a significant role in changing social issues such as crime and poverty. Social work was no longer simply a process of good will and hard work, it required the assistance of empirical study.

Allport's early motivation to use psychology to help ameliorate social problems was evident in his early course title and involvement in the Harvard department of social ethics.

For many academics involved with social ethics, part of the solution involved a shift from general amateur philanthropy to a more rigorous scientific inquiry into the subject. For Allport, a shift in terminology was important as well. Not only was Allport a central figure in the development of personality psychology as a field, but also in universalizing the term itself. The nineteenth-century focus on character development was still important, but Allport felt that the term character relied too much on moral connotations, and preferred the term personality, which he intended to refer to the objective self, which was supposed to be devoid of morally loaded characteristics. This shift was aligned with the positivistic desire to demoralize science, while at the same time attempting to preserve some of the uniqueness of the individual person.

A frequent terminological distinction used by Allport was nomothetic versus idiographic. He believed that the focus of psychology was at the time overly reliant on the nomothetic approach, which concerns general principles that are found in all people. By contrast, the idiographic approach concerned studying individuals, which of course is part of the aim of personality psychology.

Allport believed that it was important for psychology to be dynamic, as opposed to merely descriptive. For him, this meant an explanation of human motivation, rather than mere description and quantification of behavior. That is, he wanted psychology to be able to explain the why, and not just the what and how of human behavior (Allport, 1937). He also felt that other theories in psychology, such as psychoanalysis, focused too much on universal motivations, common to all humans, and not on motivations that may vary person to person. Allport argued that motivation was "functionally autonomous," that the source of motivation existed in the present and not, as behaviorists claim, in the conditioned reinforcements of past experience. Explaining the source of motivation then, became a task of studying individual traits of the person. That is, to explain behavior, we should study not the stimulus, or the person's past experience, but the person's traits.

During his lifetime, Allport played a central role in developing trait theory of personality. (see Trait theory of Allport). Allport asserted that traits were determinative, that behavior in certain situation was causally determined by traits, not just the stimulus or universal human instinct (Allport, 1931). He also believed that we could measure traits empirically or statistically, by studying people's habits. The goal is to observe consistencies in an individual's behavior that could be explained by some underlying trait. Traits though, were more generalized than simple habits. A habit could be seen as a repeated behavior, such as laughing often. A trait though, could explain the correlation between habits. For example, if the habit of laughing often was linked with the habit of frequently telling jokes, then those habits could be seen as being the result of some underlying trait.

Allport considered traits to be independent of each other, but only somewhat. Allport himself did not posit a quantitative distinction. If two traits were correlated past a certain, yet to be determined degree, then they could be said to both be determined by a more general trait. However, if they were independent past a certain degree, then they could be said to be separate traits. Allport did not describe the types or even number of traits to be standardized between individuals. In fact, he claimed that there were some universal traits, roughly maybe a few hundred, but within an individual, there could be thousands of different traits. Finding them was mainly a matter of assessing the correlations of the personsics habits.

Again, Allport emphasized that a trait was not the same as a moral quality. Traits themselves must be separated from moral qualities, as these might differ between people and populations. Instead, a trait must be objective, and universally observable, although it is possible that a trait may coincide with socially desirable characteristics. This is why Allport believed it was important, when possible, to develop terminology that removed moral connotations, as exemplified by the shift from the term character to personality. Along with Henry Odbert, Allport published an article identifying approximately 18,000 words in common use that describe patterns of behavior (Allport & Odbert, 1936). This was the first major endeavor to comprehensively search through common language in an attempt to identify trait-names for scientific measurement.

Another important aspect of traits for Allport was that behaviors that appeared to be contradictory to certain traits did not prove that the trait did not exist. He described traits in terms of frequencies of behaviors but a trait did not determine that a behavior was guaranteed in a given situation. For Allport this was partially a function of situational effects and partially a function of the prevalence of the trait itself. That meant that certain traits were more prevalent in some people than in others. This was an aspect of Allport's trait theory that differs somewhat from the way we think of traits today.

Allport conceptualized traits as falling into one of three categories in a hierarchy: cardinal, central, and secondary traits. Cardinal traits are themselves rare, and likely not even present in most personalities. A cardinal trait would be a trait that dominates a person's personality. This would likely be extremely evident and observable by anyone observing that person. However, in most people, their behavior is mostly a function of a combination of multiple traits, known as central traits, which are roughly equally involved in determining an individual's behavior. These central traits are numerous and present to certain degrees in everyone, and are generally the primary drivers of behavior. Secondary traits, on the other hand, are much less impactful on behavior and may be observable only in certain situations. They are, however, much more numerous within individuals. These secondary traits may also help explain some apparent inconsistencies regarding people's central traits. For example, when they display behavior in certain situations that appears contradictory to their central traits.

The distinction between the three categories was somewhat arbitrary and primarily served as more of a method for rating traits according to prevalence. Again, Allport claimed that few people possessed even one cardinal trait, that most of our behavior was determined by a handful of central traits, and less so by the more common secondary traits. The difference for Allport was how much influence the trait had on behavior across situations. Furthermore, the difference between one trait and another was a matter of relative, and never complete, independence. This description illustrates a somewhat fuzzy depiction of personality traits, rather than the push for fewer, but more distinct traits that we see today.

For Allport, the foundation of traits was likely physiological, but the cause could be different for different people. This was an important distinction in Allport's trait theory versus psychoanalysis and behaviorism. Rather than relying on universal, genetically determined instinct, or in unconscious motivations driven by childhood experience and sexual desire, traits could have different sources, and were dynamic. Shyness in one person could be primarily the result of genetics, but shyness in another person could be from negative past

experiences with socialization. Whatever the source, traits determined an individual's response to certain stimuli.

Throughout his career Allport worked at developing various methods of measuring personality traits. His efforts were informed by both the increasing academic demand for more objective and quantitative methods, and his own desire to incorporate the more qualitative and phenomenological approach that he developed an interest in from his time in Germany. He argued that personality can never be fully quantified or considered only in terms of individual traits, but that the person as a whole always needs to be considered. Allport referred to this later approach as the intuitive approach. Despite his efforts, the prevailing positivist attitude of the day forced him to develop more quantifiable methods for measuring personality traits. He did however attempt to maintain the importance of the uniqueness of the person by advocating the use of case studies.

It is important to note that although Allport is known as a central figure in the development of trait theory, his particular conceptualization of personality traits differ in several important ways from the way they are often defined today (Zuroff, 1986). Certain more recent definitions of traits require that they describe a pervasive consistency in behavior across situations. Generally, pervasive means across almost all situations. This definition of trait psychology is often cited in criticisms of it (see Person-Situation Interactions). Critics argue that trait psychology ignores the importance of situation when predicting behavior. Different psychologists' definitions of traits can vary. However, this is not an entirely accurate description of Allport's trait theory, which arguably has significant overlap with what is now known as interactionism (Zurroff, 1986).

Interactionist theories of personality (see Person-Situation Interactions) can be roughly differentiated into two categories: the mechanistic and the dynamic sense (Magnusson & Endler, 1977). Broadly speaking, the mechanistic sense refers to a more statistical interaction between traits and situation. That is, both the trait and the situation are needed for accurately predicting behavior, but do not actually interact with each other. In the dynamic sense, the personality trait may interact with situational variables to produce a certain behavior. For example, in a person who is comfortable around friends, but not around strangers, a situation at a party full of non-acquaintances may evoke the trait of shyness to cause the behavior of not initiating conversation with anyone at the party, this may lead to a level of discomfort that reinforces and maintains the traits of shyness for similar situations.

Most likely due to the young nature of the field, Allport was not frequently clear on his assertions regarding the interaction between trait and situation, even appearing to shift in his opinions throughout his career. However, Allport always maintained that the situation always plays some role in predicting behavior. He did not believe that a trait necessarily predicted behavior across all situations. In fact, a trait that would do that would likely constitute a cardinal trait, something that Allport explicitly stated was rarely present in anyone. For Allport, central and secondary traits were more common, but would only be present in certain situations. In other words, Allport did not require that a trait must predict behavior across all or even most situations. So Allport arguably would not be considered a trait psychologist today, at least in the strict sense. But the nature of the interaction between trait and situation for Allport is less clear.

Again, Allport considered traits to be real and determinative. He believed their source was neurophysiological, and that traits were the cause of our response to certain stimuli in

certain situations. This is in opposition to the notion that traits are merely a summary of behaviors and have no real concrete existence. Allport also believed that traits played a role in selecting situations, a view that is also common in some modern theories. However, he was less clear about the effect that situations might have on shaping traits. Although it was essential for Allport's trait theory that people did develop over time, he did not make assertions regarding the exact nature or causes of this process. Instead, much of his focus was on providing evidence for the existence of traits, at least insofar as they explain individual differences between persons.

Another noteworthy difference between Allport's traits and the more recent study of traits involves the trait constructs themselves. For Allport, individuals could have hundreds of traits, especially if both central and secondary traits are included. Also, some of these traits could contradict each other, depending on the situation. More recent models usually involve far fewer traits, such as the Five-Factor Model (FFM) (see Big Five). The more generalized nature of FFM traits allows for broader application across situations, but likely exhibits lower correlations across all situations. Allport's definitions for traits required consistency only across certain situations.

Modern theory also tends to assign people a place along a continuum for a given trait, rather than differentiating them according to a discreet hierarchy (e.g. cardinal, central, secondary). The idea is that the further toward either extreme of a given trait, the more prevalent that trait should be across situations in predicting behavior. Of course, the distribution could vary, which is part of the flexibility of modern trait theories. For example, a person could exhibit a behavior associated with a certain trait very often in a certain situation, but almost never in another situation.

Modern assessment methodology is also often different from what Allport attempted to move toward. Highly quantified tests, generalized across all persons are significantly different from Allport's emphasis on considering the person as a whole and against isolating traits individually, despite his early reliance on pencil and paper tests.

In addition to his contributions to personality psychology, Allport is also well known for his contributions to social psychology, specifically regarding prejudice. This work was likely motivated by his religious and moral character, as well as World War II, and the actions of the Nazi party in Europe. In fact, Allport was involved with the APA's efforts at the time to assist psychologists who were fleeing Europe. Allport was also involved in the Society for the Psychological Study of Social Issues. He also authored a text titled *The Nature of Prejudice*, which was to be highly influential. Allport is also frequently credited with influencing the development of humanistic psychology.

Roy F. Baumeister

Autumn D. Nanassy

Rutgers University

Roy F. Baumeister is a social psychologist internationally known for his work related to the self. Some of his notable accomplishments include work on self-esteem, free will, social rejection and belongingness, and human sexuality. Baumeister was born on May 16, 1953 in Cleveland, Ohio. His parents immigrated to the United States from Germany. Baumeister graduated from high school in 1970 as the valedictorian of his class. Although he enjoyed math during grade school, and continued to study mathematics throughout college, he began to lose interest during his second semester of college at Princeton University. He was initially switched from his math major to philosophy and religion, but as a part of a compromise with his father he began to study psychology. Baumeister subsequently attended the University of Heidelberg and then Duke University, where he received his Master of Arts degree in 1976. Throughout his early college years, he became particularly interested in individual and behavioral differences in people with high and low self-esteem (Baumeister, n.d.a).

During his graduate career at Princeton University, he studied under the influential social psychologist Edward E. Jones, who was named the 39th most cited psychologist of the twentieth century by *Review of General Psychology* (Haggbloom et al., 2002). Furthermore, Jones made notable research advancements on several concepts that relate to the self and person perception, such as the fundamental attribution error and actor-observer bias. Although Baumeister struggled to narrow down his interests and broad questions during graduate school, Jones urged him to think experimentally and scientifically. Baumeister received his PhD from the Psychology Department at Princeton University in 1978, and accepted a National Institute of Mental Health postdoctoral fellowship with the University of California at Berkeley. It was during his postdoctoral fellowship that he began to study personality and social structure.

Once his postdoctoral fellowship ended, and when he had almost given up hope (Baumeister, n.d.b.), he received a job offer from the Case Western Reserve University in Cleveland, Ohio, where he then spent the next 23 years of his career. In his autobiography, he jokes that he was the only social psychologist in his department so he had the freedom to do whatever he pleased, but also states that it may have limited him in terms of professional

development (Baumeister, n.d.b.). After his time at Case Western Reserve University, he went on to hold positions at the University of California and Florida State University, and internationally at Vrije Universiteit Amsterdam in the Netherlands and King Abdulaziz University in Saudi Arabia. He is currently a professor at the University of Queensland in Australia.

Research

Self-esteem

Baumeister's research has focused on various concepts related to the self as well as interpersonal processes. A noteworthy research interest Baumeister has explored is the concept of self-esteem. Self-esteem is defined by Baumeister as "a favorable global evaluation of oneself as whole" (Baumeister, Smart, & Boden, 1996). Research conducted by Baumeister and colleagues suggests that boosting an individual's self-esteem may not always result in positive outcomes (Baumeister, Smart, & Boden, 1996; Baumeister, Campbell, Krueger, & Vohs, 2003). Throughout the self-esteem movement, parents, teachers, and therapists had concentrated on boosting individuals' self-esteem in an attempt to eradicate a variety of issues, such as crime and pollution. Although it was believed that self-esteem could act as a buffer in stressful situations, Baumeister and colleagues noted that attempts to boost self-esteem through school programs and therapeutic interventions may not lead to positive outcomes (Baumeister, Smart, & Boden, 1996; Baumeister, Campbell, Krueger, & Vohs, 2003). To avoid inflating an individual's self-esteem arbitrarily, they suggest that self-esteem should be boosted to reward ethical behavior or achievements, as opposed to indiscriminate praise, which could just as easily promote narcissism (Baumeister, Smart, & Boden, 1996).

Baumeister and colleagues have also performed several studies, both observationally and experimentally, examining the relationship between self-esteem and violence. His research concludes that threatened egotism, not low self-esteem, leads to violent behavior. In that regard, researchers note that inflating self-esteem may be counterproductive; it may be possible to inflate individuals' self-esteem, but it would be virtually impossible to protect every person against threats to their ego. Further, higher self-esteem may actually make individuals more vulnerable to ego threats, thus resulting in more violent behaviors (Baumeister, Smart, & Boden, 1996).

In another study examining threatened egotism, narcissism, self-esteem, and aggression, results suggested that self-esteem was not directly related to aggression. In this study, the relationship between narcissism and insult was experimentally examined. Participants were randomized to receive either positive or negative feedback. Results suggested that low self-esteem and narcissism did not lead directly to violence, but rather that the aggression of narcissists was preceded by threats to their ego by means of experimentally manipulated criticism and insult (Bushman & Baumeister, 1998).

Free Will

Baumeister has examined the concept of free will, also referred to in his work as freedom of action. He has studied free will through an evolutionary lens, and declares that free will may contribute greatly to the increase in and adaptive diversity of human behavior.

Furthermore, he suggests that the two components of free will are self-control and rational intelligent choice (Baumeister, 2008). In an autobiographical study that set out to determine what free will meant to the average person, Baumeister and colleagues concluded that individuals view free will as a form of conscious control over their own actions; free actions were associated with achieving goals, conscious thought and deliberation, positive outcomes, and moral behavior (Stillman, Baumeister, & Mele, 2011).

Baumeister states that regardless of whether or not an individual believes in the concept of free will that the following facts must be acknowledged. First, most individuals believe in free will. Second, that the belief in free will can be manipulated, and this manipulation has consequences on subsequent behavior. For example, decreasing an individual's belief in free will made participants more likely to lie, cheat, steal, and hurt someone innocent, as well as make individuals less likely to help others or reflect on wrong-doings. Baumeister speculates that free will may exist to help individuals maintain self-control, make rational, intelligent choices, plan, and take initiative.

Social Rejection and Belongingness

Baumeister and Leary established that the need to belong is a fundamental human motivation (Baumeister & Leary, 1995). They propose that the need to belong consists of two aspects. The first aspect is that people desire frequent, personal interactions with the same person. Second, individuals need to perceive that there is an interpersonal connection marked by stability over time and concern for well-being (Baumeister & Leary, 1995). Furthermore, the Need to Belong Theory states that humans have a natural need to belong with others, and that lack of belonging could lead to negative health and psychological outcomes. Moreover, Baumeister distinguished that there are gender differences in the need to belong. Women prefer to have a few close, intimate relationships, whereas men prefer to belong to a group with shallower connections (Baumeister & Sommer, 1997).

Human Sexuality

Baumeister has studied several different aspects of human sexuality. Baumeister invented the term erotic plasticity, which refers to the extent one's sexual drive is shaped by cultural, social, and situational factors (Baumeister & Vohs, 2004). Overall, he concluded that women have high erotic plasticity, meaning that their sexual drives can be easily influenced by these factors, whereas men have very low erotic plasticity and have sex drives that are not as variable (Baumeister & Vohs, 2004). Baumeister has also researched rape and sexual coercion, the cultural suppression of females' sexuality, and ways in which couples negotiate their sexual patterns. Overall, this research suggests that sex can be treated as a resource in a "marketplace," where women are the sellers and men are the buyers, synonymous to an economic exchange.

Baumeister examined sexuality as it related to self-control. He noted that self-control is advantageous in the sense that it allows individuals to control their impulses and abide by social regulations, but that it is notably challenging to do so when it comes to sexual impulses. Baumeister and colleagues noted a link between low self-control and socially undesirable, inappropriate sexual behavior. Individuals with low or depleted self-control

were less likely to repress inappropriate sexual thoughts and more likely to engage in sexual activities outside of their relationship. Results suggested that diminished self-control was highest in individuals with strong sexual desires. Consequently, although not experimentally tested, researchers deducted that life circumstances that make demands on self-control are risk factors for individuals to display increasing inappropriate sexual behavior, pathological behavior, and potentially even criminal behavior (Gailliot & Baumeister, 2007).

Baumeister has also researched concepts such as self-presentation, emotion, consciousness, self and identity, self-regulation, sexuality and gender, aggression, and meaning. Throughout his career, he has written numerous books that utilize findings from the social sciences to address philosophical questions. Baumeister has written over 500 scientific articles and authored over 30 books. In 2013, he was presented with the William James Fellow Award by the Association for Psychological Science, one of their highest tributes, in honor of his lifetime achievements. He has been commended for his intellect and contributions to the field of social psychology by several experts, and will go down in history as one of the most influential social psychologists of his time (Baumeister, n.d.b.).

Jack Block

James Kean

Swinburne University of Technology

Background

Professor Jacob "Jack" Block was born on April 28, 1924. Block's parents immigrated to New York together. His mother was from Russia, more specifically from Byelorussia, now known as Belarus, and his father was Lithuanian. At 14-months old, Block's father passed away and he was raised by his single mother in New York, who continued to run the jewelry store his father operated before he died. Block attended PS2 public school in Brooklyn, New York, and then Stuyvesant High School in New York. During high school, Block delivered tuxedos for a local tailor for $2.00 a day on Saturdays to make some money. After enrolling in Brooklyn College at the age of 16 he felt unhappy and was not doing well, leaving after the first year. Block worked as a machinist for a while and despite being a good machinist, grew bored with the work and returned to Brooklyn College. He continued to struggle with academic life, earning a GPA of 2.23, a feat he notes as being "the lowest undergraduate grade point average of anybody" (personal communication, May 1, 1994). Despite this, he earned his bachelor's degree and because he was a three varsity letter athlete at Brooklyn College (swimming, wrestling, and football), the first ever, was accepted by New York University (NYU). Block had begun taking pre-med courses at Brooklyn before graduating, but had not completed many by the time he started at NYU and so he enrolled himself as two students (with the same name) in order to complete his pre-med courses sooner. It was only due to the fact he was doing so well, that Block was allowed to continue even after his ruse was discovered. He applied to attend the University of Wisconsin despite the semester having already started and so was required to submit his manuscripts from previous colleges. Luckily for Block, NYU were prompt, sending his manuscript that highlighted Block's academic prowess with a host of straight As, whereas Brooklyn College, at which his GPA was the lowest of anyone, was delayed. However, by the time the Brooklyn College transcript was received, he was already enrolled at Wisconsin. He went on to complete his Masters in 1946. In 1947, following a number of rejections by medical schools due to his overall grade point average, Block was again rejected by the Stanford Medical School,

but was accepted by the Stanford Psychology Department. From there, Jack settled into a PhD at Stanford University with a major in the field of psychology, and minors in sociology and physiology. During his time at Stanford, Jack met Jeanne, another PhD student with remarkably similar research interests to his own. The two PhD students began to take classes together and it was not long before they began to collaborate on ideas and combine their research efforts. At the conclusion of their studies at Stanford in 1950, Jack and Jeanne were not only married, but had combined their theses, with Jack graduating in 1950 and Jeanne in 1951. The couple had developed concepts on *ego-control* and *ego-resiliency* as underlying mechanisms for understanding motivation, emotion and behavior (Block & Block, 1980). These ideas would formulate their life's work. Jack focused his work on personality development and its capability of change throughout the lifespan. His research conflicted with many accepted ideas in personality theory. Jack's research highlighted the consistency with which people maintained particular personality traits, regardless of the environment they were in, which opposed the idea that personality was more dynamic and would adjust depending on the environment the person was placed in. His most stark contrast was his belief that a personality construct could not be limited to, and tested on the basis of the five broad traits commonly associated with personality theory today. Professor of Psychology at University of California Berkeley, Jeanne Block, passed away on December 4, 1981. Professor Emeritus Jack Block continued to lead their joint longitudinal study until he passed away in 2010. Jack and Jeanne are survived by their four children Susan, Jody, David, and Carol Block as well as four grandchildren Brian, Robert, Josh, and Gabriel.

Major Contribution: The Block and Block Longitudinal Study

In 1968, Jack and Jeanne Block began their 40-year long research study into human development. The pair recruited 128 children from nursery schools. The two core themes of their work investigated the concepts of *ego-resiliency* and *ego-control*. The latter, ego-control, investigates the degree to which a person is capable of delaying gratification in the service of obtaining future goals. The outcomes provide information on an individual's ability to inhibit impulsive behaviors as well as forecast future outcomes based on decisions made in the present. Ego-resiliency, which is intertwined with ego-control, highlights an individual's "invulnerable survivorship," which is to describe their ability to maintain consistency regarding these impulses when placed in new and challenging environments (Block & Kremen, 1996). Research in developmental neuroscience has since identified their findings to reflect an adaptation of the individual in new environments, despite poor early childhood attachment experiences (Arend, Gove, & Sroufe, 1979). The two components encompass what Block called *observable phenomena of motivational control and resourceful adaptation* and spent his career highlighting their key place in understanding a person's personality (Block & Kremen, 1996, p. 351). The participants were followed-up for the next 40 years.

Following the passing of Jack and Jeanne, Jack chose the University of California Santa Cruz to continue their life's work. Developmental psychologists Avril Thorne, Per Gjerde, and David Harrington continue to follow up the participants (now in their fifties) and analyze the mountainous levels of data collected since 1968.

Other Notable Works: The Q-Sort Method in Personality Assessment

Jack Block devised a method for quantifying the normally subjective methods involved in personality assessment. Block noted that many of the assessments of the day made by professionally trained experts in the personality field were unreliable due to the subjectivity of the observer. The method utilizes the key components of personality combining multiple theoretical frameworks so as to ensure the strengths of each clinical viewpoint is incorporated. In the method, an observer is given a set of 100 statements that describe basic characteristics of the person from their mannerisms in social situations, to their level of intelligence, to the way they express emotion. One unique aspect of the technique is that the individual, rather than the variable(s) under study, is the subject of factor analysis. This is the inverse direction to more common factor analytic techniques and it enables the observer to identify the subject as being one of three personality types *resilient, overcontrolled*, or *undercontrolled* (Weir & Gjerde, 2002) as originally defined by Block. The method is used specifically to elucidate observer-evaluations of an individual that can then be compared to other observations on a uniquely independent basis. The Q-sort method of personality assessment went on to be called the California Child Q-Set (CCQ) and the California Adult Q-Set (CAQ), which are still used today.

Acknowledgments and Awards

Jack Block was awarded multiple fellowships during his academic career including the Buckel Fellowship at Stanford University in 1948, the Social Science Research Council Summer Fellow, 1954 and then again in 1958, the Foundation Fund for Research in Psychiatry Fellowship in 1960 and the National Institute of Mental Health Special Research Fellowship from 1963 to 1964. Following this, Black was awarded the James McKeen Cattell Fellowship from 1978 to 1979, the Humphrey Fellowship at Ben-Gurion University in Israel in 1987, became a Fellow for the American Association for the Advancement of Science and finally was elected to fellow status within the American Psychological Association in Divisions 1, 5, 7, 8, and 9.

Professor Jack Block was awarded the Hofheimer Prize for Research granted by the American Psychiatric Association. He received the Appleton-Century-Crofts Award for the book, *The Challenge of Response Sets* in 1965. In 1985, he received the Henry A. Murray Award within the Division of Personality and Social Psychology, from the American Psychological Association. In 1990, received the G. Stanley Hall Award within the Division of Developmental Psychology from the American Psychological Association. The Society for Research on Adolescence presented him with the Social Policy Award for his work on drug usage between 1990 and 1992. In 1998, he was awarded the Bruno Klopfer Award for advancing the field of personality assessment. Finally and most fittingly, Jack Block was awarded Saul B. Sells Award for his lifetime of achievements presented to him by the Society of Multivariate Experimental Psychology, 1998.

Conclusion: Personality and Individual Differences

Professor Emeritus Jack Block dedicated his life to the meticulous work in personality assessment and developmental psychology, contributing to the field for over 60 years. His work with his wife, Jeanne has become one of the most historical longitudinal studies in personality psychology in the world. His work in longitudinal studies continued with the publication of the book *Lives Through Time* (1971) describing the remarkable stability of an individual's personality over long periods of time, contrasting with the theories of the time that described personality as more malleable and changing. The Block and Block Longitudinal study continues to this day, a legacy that will provide monumental data for the generation of personality psychologists.

David M. Buss

Sarah E. Babcock

The University of Western Ontario

Background

David Buss was born April 14, 1953 in Indianapolis, Indiana, to parents Arnold H. Buss and Edith H. Buss. He has early roots in psychology, as his father earned his PhD in Psychology from Indiana University in the early 1950s and went on to be a professor of psychology at the University of Pittsburgh, Rutgers, and the University of Texas. David Buss followed in his father's academic footsteps, pursuing psychological studies. He earned his Bachelor of Arts degree from the University of Texas in 1976 and continued into his PhD in Psychology at the University of California, which he completed in 1981. His early academic career began in 1981 as an assistant professor at Harvard University, where he remained for four years. He then moved on to conduct research and instruction at the University of Michigan, where he was an associate professor for four years and then a professor for five additional years. After his time at the University of Michigan, he moved onto a professorship at the University of Texas, where he is still currently positioned. In his current role as a full professor, David Buss is the head of the Individual Differences and Evolutionary Psychology Area at the university, and actively conducts research, teaching, and supervising graduate students in the field of evolutionary psychology.

Major Research

Buss was a trailblazer in the field of evolutionary psychology. His early work describing sexual behavior in the context of human evolution theory revolutionized the current thinking in human mate selection, retention, and adaptive romantic relationship behaviors. Before discussing Buss' primary contributions and positions in the field, it is important to understand what the discipline of evolutionary psychology entails. As a brief summary, evolutionary psychology is a diverse and complex field, which combines insights from a variety of disciplines, including: evolutionary theory, biology, psychology, cognition,

economics, and anthropology. Overall, the field rests on a few core premises, which include: (1) manifested behavior depends on underlying psychological mechanisms, (2) evolution by selection in the only causal process capable of creating such complex organic mechanisms, (3) evolved psychological mechanisms are functionally specialized to solve adaptive problems, (4) selection designed the information processing of many evolved psychological mechanisms to be adaptively influenced by certain information in the environment, and (5) human psychology consists of a large number of functionally specialized evolved mechanisms, each sensitive to particular contextual input.

Returning to Buss' core contributions, Buss' primary research focuses on human mating strategies. He is best known for his studies on mate selection, tactics of mate attraction and retention, and the mating emotions of jealousy, love, and lust. In his early work, he began discussing the psychology of sexual selection in the context of Charles Darwin's human evolution theory. He posited that modern humans are similar to their historical ancestors, employing strategies that are best suited for their biological and evolutionary needs, depending on their sex. Despite a modern society, Buss strongly articulates that these sex differences exist for men and women due to evolutionary adaptation. He suggests that the diverse adaptive challenges that the sexes have faced throughout evolutionary history are the primary determinants shaping the behavioral differences observed between males and females in their sexual and relationship strategies today, even in our modernized world. A comprehensive summary of this position is detailed in the book *The Evolution of Desire: Strategies of Human Mating* (Buss, 1994). Gender differences in the context of evolutionary theory are also discussed in the entry titled Gender differences / evolutionary. Another primary research stance of Buss' is the idea that in a mating relationship, females will prioritize commitment while males will prioritize reproducing offspring. Buss proposed Strategic Interference Theory, which suggests men and women deal differently with intersexual deception. Buss separates the concepts of emotional and physical infidelity, suggesting that women will be more anxious about their mate's *emotional* infidelities, while men will be more concerned about *sexual* ones. Therefore, female jealousy originates from "threat to commitment," while jealous behavior in men arises from the fears of "paternity uncertainty." For a detailed examination of how jealousy and relationship threat manifest in the context of this theory, see the book *The Dangerous Passion: Why Jealousy is as Necessary as Love and Sex* (Buss, 2011) and further, the entry titled Evolutionary theory and personality correlates of mate As a part of Dr. Buss' research program, his contributions have also involved the development of many research instruments to collect data within this field. One such example includes the Jealousy Instrument (Buss et al., 1999), which captures participant information regarding relationship status, quality, issues of infidelity, and relationship concerns. Another example is the Mate Attraction Tactics survey (Bleske-Rechek & Buss, 2006) which captures information about the behaviors and approaches individuals engage in to attract a potential mate. These tools (and many others) are readily available on his lab website.

Buss leads several active research programs at the University of Texas at Austin, including specializations in mating emotions and the psychology of prestige and status. Moreover, his most recent research has focused more heavily on the darker side of human nature and romantic and sexual relationships. Specifically, he is conducting research on partner jealousy, stalking behavior, as well as intimate partner violence and murder. This research is guided by the conceptual frameworks anchored in evolutionary psychology.

Authored Books and Popular Press

Given the strong link to love, sex, and relationships, and the importance of these topics in our modern world, his work is frequently featured in the popular media. This includes appearances on nationally syndicated televised programs and scientific documentaries, article and commentary features on psychology in multiple popular-press magazines, and other digital media outlets. David Buss has been an invited speaker and keynote address to over 40 psychological association conferences (including the American Psychological Association, the Association for Psychological Society) as well as numerous universities and academic institutions, and corporations.

In addition to his over 200 published academic articles (see Buss' CV, as per the University of Texas departmental lab website, 2018), Buss has also had many written features in a variety of popular psychology outlets, and has authored several books for wide-ranging audiences, from academic scholars to university students and the general public. His textbooks include: *Personality Psychology: Domains of Knowledge About Human Nature* (Larsen & Buss, 2017), *Evolutionary Psychology: The New Science of the Mind* (Buss, 2016), and *The Handbook of Evolutionary Psychology* (Buss, 2005a). In addition to academic textbooks, Buss has also authored several books for public audiences, including: *Why Women Have Sex: Women Reveal the Truth About Their Sex Lives, from Adventure to Revenge (and Everything in Between)* (Meston & Buss, 2009), *The Evolution of Desire: Strategies of Human Mating* (Buss, 2008), *The Murderer Next Door: Why the Mind is Designed to Kill* (Buss, 2005), *The Dangerous Passion: Why Jealously is as Necessary as Love and Sex* (Buss, 2011) and *Sex, Power, Conflict: Evolutionary and Feminist Perspectives* (Buss & Malamuth, 1996).

Acknowledgments and Awards

Buss' awards and honors are numerous. As an early researcher, Buss was awarded the 1988 APA Distinguished Scientific Award for Early Career Contribution to Psychology (American Psychological Association, 1989). Moving forward, Buss continued to be acknowledged for his work and extraordinary contributions to the field of psychology. Alongside many distinguished faculty and fellow acknowledgments and honors over the past 30 years, Buss has also been presented with the G. Stanley Hall Lecturer Award (1990), the APA Distinguished Scientist Lecturer (2001), and the 27th Most Cited Psychologist in Introductory Psychology Textbooks (2003). He has been named as one of 30 Most Influential Psychologists (2013), and the Most Eminent Psychologists of the Modern Era (2014). A detailed list of his awards can be found on his CV, located on his lab website (2018).

Paul T. Costa Jr.

James Kean

Swinburne University of Technology

Background

Paul T. Costa Jr. was born on September 16, 1942 to Paul (Sr.) and Esther Costa, in Franklin, New Hampshire. His mother Esther, a renowned figure in radio broadcasting, spent time interviewing several prominent figures of the time, including Eleanor Roosevelt and the matriarch of the Kennedy family, Rose "Countess" Kennedy, mother of nine children, including President John F. Kennedy.

In 1964, Professor Costa earned his undergraduate psychology degree from Clark University. Costa went on to complete two master's degrees in human development in 1968 and 1970, both at the University of Chicago. Between 1970 and 1972, Costa completed his PhD and went on to teach at Harvard University until 1973 where he moved to the University of Massachusetts, Boston. In 1975, following a collaboration with Professor James Fozard, a young budding PhD student was referred to him by the name of Robert McCrae. In 1976, Costa hired McCrae as a director for a Smoking and Personality project grant they had received. In 1978, Costa became the Chief of the Section of Stress and Coping and continued to work on the project with McCrae for two years. In 1985, Costa became the Chief for the Laboratory of Personality and Cognition, and was then awarded the title of President of the Adult Development and Aging division of the American Psychological Society. In 1995, Paul Costa became the President of the International Society for the Study of Individual Differences. During the many fruitful years of his career, Paul Costa also had a fruitful marriage with his wife Karol Sandra Costa, having three children, Nhia, Lora, and Nicholas.

In 1967, Costa published his first article on memory and ambitions in centenarians in the *Journal of Genetic Psychology*. The publication hinted at what Costa would later dedicate most of his work to, asking the questions that may help him explain the fundamentals of personality "How does the centenarian integrate his extensive past experiences with his present moment of existence?" (p.3). Since this initial piece of writing, Costa has written over 300 academic articles and several books, which have earned him over 125,000 citations

to date with an average of just over 8,800 citations per year between 2013 and 2017. His work has made him one of the most cited living psychologists in the world.

Major Contribution: The Neuroticism-Extraversion-Openness to Experience Personality Inventory (NEO-PI)

In 1975, one of the most successful psychological research partnerships would begin upon a chance referral from a psychologist in common – Professor James Fozard. In 1976, Paul Costa hired the recent doctoral graduate student Robert McCrae as a project director for a Smoking and Personality Grant. After working side by side for two years on the project, the pair had developed a working relationship that would last well into the new century, and continues today. In 1972, Costa co-authored a book with Salvatore R. Maddi on humanistic personality theory titled *Humanism in Personology: Allport, Maslow and Murray*. The book explores the ability of man to possess both freedom and dignity despite the antagonistic environment he finds himself in (Maddi & Costa, 1972). The text investigates the benefits of conducting psychological research in as natural a setting as possible, with limited numbers of controls, allowing the researcher to obtain as pure a form of behavioral data as possible. This initial publication set the tone for Costa's later personality work with McCrae, looking deep into to the humanistic elements of an individual's subjective experience.

The pair continued to work in Baltimore, Maryland within The National Institute on Aging's Gerontology Research Center. The database contained within the research center allowed the duo access to datasets of considerable size, ideal for measuring the consistency of personality dimensions in large cohorts. This led the research team to compose a pivotal publication in the development of their personality theory – *Age Differences in Personality Structure: A Cluster Analytic Approach* (Costa & McCrae, 1976). The publication utilized the factor analytic work by Raymond Cattell, dividing up the well-established 16 personality factor questionnaire into age groups and elucidating which factors remained stable over time. In this case *anxiety-adjustment* and *introversion-extraversion* were the two consistent dimensions of personality that were deemed stable over time. Following on from this work, the pair discovered that besides the previously agreed upon traits of Neuroticism (N) and Extraversion (E) there was a clear dimension they denoted Openness to Experience (O). This led to the first ever version of their personality inventory including these three factors (Costa & McCrae, 1978), which they went on to call the Neuroticism-Extraversion-Openness Inventory (NEO-I) (Shock et al., 1984). Thanks to their continued work on the Baltimore Longitudinal Study of Aging, the inventory was revised to include two more factors denoted Agreeableness (A) and Conscientiousness (C) (Costa & McCrae, 1985). In 1985, the inventory was renamed the NEO-Personality Inventory (NEO-PI) and contained each of the five traits (Neuroticism, Extraversion, Openness to Experience, Agreeableness, and Conscientiousness), also known as the Five Factor Model (FFM). The personality factors were each measured using 48-items per factor, and each of them was broken down into six sub-scales (denoted *facets*), with the last two factors (A, C) measured using only 18-items with each factor. The test totaled 181-items with the validation questions confirming the truthfulness of the answers provided by the participant. Research using the inventory indicated that each factor was consistent and useful in understanding the depth of the personality of the person completing it.

In 1992, Costa and McCrae revised the inventory, with six facets per factor, 30 facets in total, and it became one of the only personality inventories to measure all five factors now well-established as part of the individual personality structure (Costa & McCrae, 1992). The revised manual of the NEO-PI-R and the NEO-FFI, a short form of the test, has been cited approximately 24,000 times since its publication.

Major Contribution: Since the NEO-PI-R and the NEO-FFI

Since the beginning of their collaboration, Costa and McCrae have published over 200 articles, books, book chapters together over 40 years. In 2003, the pair published the book *Personality in Adulthood: A Five-Factor Theory Perspective,* 2nd ed. The book examines the personality traits and dispositions of the individual and the impact these have on the processes of aging and behavioral development (McCrae & Costa, 2003).

   Costa has since argued that personality is a universal construct that is stable over time, particularly after the age of 30 and that an individual's core personality can be assessed using the five major factors, that in-turn reflect a unique constitution of individual facets. This intricate structure of personal habits lies at the core of a person's long-term behavior.

Acknowledgments and Awards

Paul Costa Jr. is an Adjunct Professor of Psychology within the Duke University Medical Center (DUMC) within the Department of Psychiatry and Behavioral Science. Among his many accomplishments, Costa has been elected to *Society of Multivariate Experimental Psychology*; he was elected President for the Division on *Evaluation, Measurement and Statistics*, Division 5 of the American Psychological Association (APA). In 2004, at the 112th Annual APA Convention, Costa was awarded the *Arthur Staats Award Winner Address on Unifying Psychology*, for his lecture on the FFM and the FFT.

   In 1993, Costa received the *Distinguished Contribution Award*, *Division 20* (Adult Development and Aging, APA) followed in 1994 by the *NIH Director's Award,* and then in 1995 through to 1997 was elected President of the *International Society for the Study of Individual Differences*. In 1997, Costa was elected to *Academy of Behavioral Medicine and Research Fellow*, Division 5 (Measurement, Evaluation and Statistics), for the APA and then in 1999 elected to the *Academy of Behavioral Medicine and Research*. In 2009, Costa was made a Fellow of the APA and was also awarded the *Jack Block Award* winner, for the Society of Personality and Social Psychology.

Conclusion: Personality and Individual Differences

Professor Paul Costa is a distinguished psychologist and research fellow within the world of personality and individual differences. His own work as well as his remarkable collaboration with Robert McCrae has provided the field with an immense amount of data and evidence that has significantly enabled researchers, psychologists, and clinicians to better understand the intricate details of the human personality.

Robert McCrae

James Kean

Swinburne University of Technology

Background

Robert Roger McCrae was born on April 28, 1949 to Andrew and Eloise Elaine McCrae. He was born in the small town of Maryville, Missouri and was the youngest of three children. In 1971, McCrae completed a degree in philosophy at Michigan State University, after which he transitioned to the field of psychology for his graduate Masters studies at Boston University. As a young man McCrae had a passion for science and mathematics, and upon witnessing the combination of those two subjects by esteemed psychologist Raymond Cattell, McCrae became fascinated by the subject of personality and its assessment. Cattell used a statistical technique known as factor analysis to break down the facets of human personality and intelligence, providing researchers, clinicians, and psychologists a more precise and empirically based explanation for the core aspects of the human psyche. McCrae worked alongside psychologist Professor Henry Weinberg during his graduate studies at Boston University, who recognized but did not share McCrae's passion for personality research. In 1974, McCrae began his doctorate in Personality Psychology at Boston University, investigating the intricacies of the human personality, albeit without much assistance or kudos from colleagues. He regularly refuted the notion that an individual's personality was more of a reflection of their environment and that a person's personality was a malleable construct, capable of variation. Over time, McCrae's work would overturn these views, providing a statistically sound explanation for the construct and consistency of the individual personality. In 1976, McCrae completed his PhD.

In 1976, McCrae was hired as project director by fellow personality psychologist Paul Costa for a recently awarded grant in personality and smoking. Following this work, the pair were offered a position at the National Institute of Health within the Gerontology Research Center that forms part of the National Institute on Aging in Baltimore, Maryland. McCrae was awarded a position as Senior Staff Fellow. During this time, the pair worked tirelessly on the idea that the human personality is made up of "traits," a distinctive characteristic that an individual might exhibit differently from another. This type of research

contradicted the accepted thinking at the time that said traits were unable to explain the way the personality was constructed.

Robert R. McCrae currently resides in Massachusetts continuing to publish his research on the foundations of personality and individual differences (McCrae, 2018) as well as maintaining his passion for classical music and cooking.

Major Contribution: The Neuroticism-Extraversion-Openness to Experience Personality Inventory (NEO-PI)

In 1975, a professor at the Veterans Administration Outpatient Clinic in Boston by the name of James Fozard, appointed a new research assistant – Robert McCrae. It was not long before McCrae was further referred to another psychologist, but this time, one with a distinct interest in the assessment and perception of the human personality. In 1976, Professor Paul Costa hired the recent doctoral graduate student Robert McCrae as a project director for a Smoking and Personality Grant. After working side by side for two years on the project, the pair had developed a working relationship that would last well into the new century, and continues today. In the same year, the pair published their first article together investigating the personality composition of 472 males using the Cattel 16-Personality Factor test (16-PF; Cattell et al., 1970). The publication titled *Age, Anxiety and Self-reported Health*, revealed that those people who were rated as *anxious* reported increased levels of health problems in younger and middle-aged cohorts, but not in the older cohort. The conclusion was that older males do not waste any time dealing with health issues due to the limited amount of lifetime they had left and through this symptom denial, reductions in the level of anxiety were experienced.

During their time on the Veterans Administration's Normative Aging Study, the team had access to a sizable database, allowing them to investigate the similarities and differences in personality structure of a large cohort. This led to a pivotal publication in the development of their personality theory – *Age Differences in Personality Structure: A Cluster Analytic Approach* (Costa & McCrae, 1976). The publication applied the factor analysis work by Raymond Cattell, to his 16-PF test, to break down the factors into weighted components, which included the dimension's anxiety-adjustment and introversion-extraversion. The previously established traits of Neuroticism (N) and Extraversion (E) did not comprehensively explain all aspects of the individual personality structure. The factor analysis work uncovered one other domain known as Openness to Experience (O). This led to the first ever version of their personality inventory including these three factors (Costa & McCrae, 1978). This was denoted as the Neuroticism-Extraversion-Openness Inventory (NEO-I) (Shock et al., 1984).

After 1978, Costa and McCrae continued to work in Baltimore, Maryland within The National Institute on Aging's Gerontology Research Center. As they continued to break down the structure of personality, the pair located and described two more unique factors, denoted Agreeableness (A) and Conscientiousness (C) (Costa & McCrae, 1985). In 1985, this led to the inventory being renamed the NEO-Personality Inventory (NEO-PI) and contained each of the five traits we know today – Neuroticism, Extraversion, Openness to Experience, Agreeableness, and Conscientiousness. This also went on to be known as the Five-Factor Model (FFM). Within the model, each trait (factor) was broken down into six

facets with the test totaling 181-items including validation questions confirming the truthfulness of the answers provided by the participant. Research using the inventory indicated that each factor was consistent and useful in understanding the depth of the personality of the person completing it. In 1992, the inventory was revised with six facets per factor, 30-facets in total, and it became one of the only personality inventories to measure all five of the now well-established trait factors (Costa & McCrae, 1992). The revised manual of the NEO-PI-R and the NEO-FFI, a short form of the test, has been cited approximately 24,000 times since its publication.

Major Contribution: Since the NEO-PI-R and the NEO-FFI

Since the beginning of their collaboration, Costa and McCrae have published over 200 articles, books, and book chapters together over 40 years. In 2003, the pair published the book *Personality in Adulthood: A Five-Factor Theory Perspective,* 2nd ed. The book examines the personality traits and dispositions of the individual and the impact these have on the processes of aging and behavioral development (McCrae & Costa, 2003).

McCrae's work on the correlations of personality at a cultural level highlighted some unique findings in a country's power index – a metric that describes the distribution of power and wealth between individuals of that country. This piece of anthropological work was carried out by McCrae in collaboration with the creator of the term Power-Distance Index (PDI) Professor Geert Hofstede. The findings indicated that countries low in extraversion and high in conscientiousness are much higher in PDI, that is, they tend to rely on a distinct hierarchy of authority (Hofstede & McCrae, 2004). This method of research provides distinct insights into the way countries tend to operate at a national level.

McCrae continues to argue that the individual personality is a stable, universal construct. This intricate structure of personal habits, facets, and traits lies at the core of a person's long-term behavior. McCrae's work has received approximately 130,000 citations with over 50,000 citations in the past five years.

Acknowledgments and Awards

Professor Robert R. McCrae was awarded the National Merit Scholar in 1967 at the beginning of his university degree. He was nominated for a Woodrow Wilson award in 1971. In 1984, he was awarded a fellowship for the American Psychological Association (APA) (Division 20), for the APA in 1991, for the APA (Division 5) in 2006 and lastly for the APA (Division 8) in 2016. In 1992, he obtained a fellowship of the Gerontological Society of America. In 2013, McCrae was awarded the Bruno Klopfer Award as part of the Society for Personality Assessment as well as the Jack Block Award for the Society for Personality and Social Psychology. Finally, on two separate occasions, he was designated Distinguished Lecturer for G. Stanley Hall at Johns Hopkins University and Multicultural Psychology for Michigan State University.

Robert McCrae has also sat on several journal and societal committees as well as being a key reviewer for several significant periodicals.

Conclusion: Personality and Individual Differences

Professor Robert McCrae is a distinguished psychologist and research fellow within the world of personality and individual differences. His own work on cultural differences and stability as well as his remarkable collaboration with Professor Paul Costa has provided the field of personality study with a significantly better understanding of the intricate details of human personality.

Ed Diener

Kristin Layous

California State University, East Bay

Ed Diener, PhD, (born 1946) pioneered the study of subjective well-being (SWB; a combination of one's satisfaction with life, frequency of positive emotions, and infrequency of negative emotions) by creating sound measures and exploring the relationship between SWB and a wide range of other consequential personal attributes (Diener, Suh, Lucas, & Smith, 1999). Additionally, Diener championed the study of SWB on a global level (Diener, 2000), exploring cultural influences on well-being, as well as the relationship between income and SWB. At the time of this writing, Diener has contributed over 340 scholarly works, that have been cited 136,000+ times (according to Google Scholar) leaving an enduring mark on the field of psychology and establishing subjective-well-being as a respected field of study. Diener is currently the Joseph R. Smiley Professor of Psychology Emeritus at the University of Illinois, where he has been a faculty member since 1974, and is also a professor at the University of Utah and the University of Virginia, as well as a Senior Scientist at the Gallup Organization.

Personal Life

Diener was born in Glendale, CA in 1946, the youngest of six children. His love of family and appreciation for the values his parents instilled in him permeate his autobiography, which he calls a "periodic update" due to his life still having many years to unfold (Diener, 2008). He praises his parents and siblings for giving him an early sense of meaning in life and instilling in him a desire to help the world in some way. His dad was a successful farmer and although his parents were wealthy, Diener states that money was never his parents' end goal. Instead, they sought to perform good works whenever possible, donating their time and resources to various charities, a trend which you can see in Diener's life as well.

Diener describes himself as an intensely curious person, an attribute that has fueled his motivation and productivity in his research career, but also got him into some trouble as a child. He notes that one time he threw a rock into a swarm of bees just to see what would

happen and, unsurprisingly, he did not like the answer (Diener, 2008). Diener was a sickly child, which meant that he spent a lot of time indoors indulging his curiosities with activities like rolling a dice over and over again and teaching himself how to calculate probabilities. Diener showed an early love of math and statistics, which is apparent in his extensive body of empirical papers. Diener's father also had a love of numbers and he had hoped that Diener would apply his curiosities to the agricultural field as he had done, but Diener states that he was always drawn to uncertainty and thus the field of psychology, with its less predictable nature, drew him in (Diener, 2008).

During high school, Diener met the love of his life, Carol, and they dated for four years before getting married during their junior year at Fresno State (also known as California State University, Fresno). They had their first children two years after that in 1968, the fall after they graduated from college (twins, Marissa and Mary Beth) and their son, Robert, in 1972, while Diener was in graduate school. Diener describes parenting as a rewarding experience – so rewarding that he and Carol decided to foster five children (all about 10 years old) and then ultimately adopt two of them, Kia and Susan, for a total of five children (Diener, 2008).

After graduating from college, Diener was drafted to go to Vietnam, but registered as a Conscientious Objector. In place of military service, the draft board assigned him to two years of working at a psychiatric hospital. At the time, Diener thought he wanted to go into clinical psychology, so he was excited that the assignment would give him the necessary experience to be a competitive applicant for PhD programs. Instead, Diener learned that he did not enjoy working with clients. Through a variety of promotions, Diener found himself as the administrator of a new hospital, which also taught him the valuable lesson that he did not enjoy being an administrator. Equipped with these lessons and a continuing love of the field of psychology, Diener realized his true passion was research and he obtained a research-based PhD in Psychology at the University of Washington (1970–1974).

In 1974, Diener took a tenure-track position at the University of Illinois, where Carol started a PhD program in clinical psychology. Diener has said that one solution to balancing family with research was to incorporate family into his work. He often took his children to his lab and talked to them about psychology around the dinner table. All three biological children ended up with careers in psychology. Diener jokingly says that he and Carol think it "must be genetic" but he notes an alternative explanation that Kia and Susan did not come into their family until they were 10 years old, thus missing some of the early indoctrination (Diener, 2008).

Diener has now engaged in over four decades of impressive scholarship at the University of Illinois (much of which is detailed later). In addition, Diener joined the Gallup Organization as a Senior Scientist in 1999 and joined the faculty of the University of Utah and the University of Virginia in 2015.

Early Research Career: Deindividuation

Diener had an early interest in happiness and its correlates. At Fresno State, he asked whether he could assess the happiness of migrant farm workers for a course project. His professor rejected his proposal on two accounts: (1) farm workers are not happy, and (2)

there is no way to measure happiness. Appropriately, Diener conducted his research project on conformity (Diener, 2008). Given the prevailing notion that happiness was unmeasurable and flaky, Diener did not pick the topic back up until after he had tenure at the University of Illinois.

During graduate school at the University of Washington, Diener had three main mentors. Irwin G. Sarason and Ronald E. Smith taught Diener the basics of personality psychology and multimethod measurement, and with them he wrote a review paper during the person-situation debate demonstrating that, even when situations affect behavior, personality often simultaneously affects behavior, as does the interaction between personality and situation variables. With Scott E. Fraser, Diener worked on a series of deindividuation studies, which formed the crux of Diener's pre-tenure empirical work.

Because of the riots of the 1960s and the continuing anti-Vietnam War demonstrations, Diener was interested in crowd behavior and more specifically in the idea of deindividuation – the loss of self-regulation in groups. In a series of elaborate and cleverly designed studies, Diener and colleagues systematically tested the prevailing ideas about what conditions led to deindividuation, what feelings and thoughts composed an internal deindividuated state, and whether the internal deindividuated state could be linked to disinhibited behavior (e.g. antinormative behavior like aggression and stealing or just odd behavior like finger painting with one's nose; e.g. Diener, 1979).

To test possible causes of aggression, Diener created the "beat the pacifist" dependent variable in which, after an experimental induction, he directed participants to enter into a room with a confederate sitting on the floor and instructed them to "do various things to him" with provided materials (e.g. crumpled up newspaper balls for throwing, a large bowl of rubberbands for shooting or snapping, Styrofoam swords for hitting). Telling participants that they would not be responsible for their actions, justifying the activity by saying it was a game, being primed with an aggressive video, and exercise-induced arousal all increased aggression. In another clever paradigm, Diener and colleagues manipulated anonymity and felt responsibility among Halloween trick-or-treaters in a naturalistic experiment. Trick-or-treaters were instructed to only take one candy before the experimenter ostensibly left them to their own devices. Children who were left anonymous (not asked their name or where they lived) were more likely to take extra candy, as were children who appeared in groups versus those who appeared alone. If all groups members were left anonymous and the experimenter placed all blame on one child (altered responsibility), transgression rates were the highest (80%).

Although Diener and colleagues' research supported the presence of situational variables that increased disinhibited behavior, he was not reliably able to relate these external conditions to an internal deindividuated state and, in turn, was not reliably able to relate an internal deindivudated state to the disinhibited behavior. Given these mixed findings, Diener and colleagues called for clearer definition and measurement of what constitutes disinhibited behaviors and the internal state of deindividuation. For example, he called for research and conceptual clarity on the potentially differential effects and precursors of an internal self-awareness versus a public self-consciousness, a challenge that other researchers accepted. In 1979, Diener earned tenure and changed the focus of his research to subjective well-being.

Subjective Well-Being

Diener describes himself as a sensation seeker and a noncomformist, which led him to much mischief in his childhood and beyond, but also gave him the willingness to explore unpopular topics that he found interesting (Diener, 2008). When Diener started working on well-being research, it was not viewed favorably by the research community – it was too fluffy and unmeasurable. Diener notes that his promotion to full professor was blocked for a year or two because of these negative attitudes toward well-being research (Diener, 2008). Nevertheless, during Diener's sabbatical year in 1980, he spent a year reading the 18 books and 220 articles he could find on subjective well-being (SWB) and wrote a review paper published in *Psychological Bulletin* assessing the state of the field and covering important issues that Diener would study over the years such as the theories, measurement, causal influences, and demographic correlates of SWB. Throughout Diener's work on SWB, he focused on sound and rigorous empirical methods to lend legitimacy to the science of SWB and its importance as a field of study. Although Diener's contributions to the science of SWB are too numerous to name, the following is a sampling of his contributions.

Theories and Measurement of Well-being

Diener has provided theoretical and empirical support for the predominant definition of SWB as a broad category composed of three independent but related constructs: a cognitive evaluation of one's life (life satisfaction), frequency of positive affect, and frequency of negative affect (Diener et al., 1999; Lucas, Diener, & Suh, 1996). To further the science of SWB, Diener created and validated the most commonly used scales to measure these constructs, with his Satisfaction with Life Scale being cited over 15,000 times (Diener, Emmons, Larsen, & Griffin, 1985) and his affect scales also being widely used (e.g. Diener & Emmons, 1985; Diener et al., 2009). While SWB research came under scrutiny for using primarily self-report methods, Diener and colleagues provided empirical evidence that self-reports of well-being were not simply response artifacts of social desirability or current mood, but rather could accurately reflect the stable trait of life satisfaction, and relate well to various non-self-reports of SWB across construct validation studies (e.g. Lucas et al., 1996). This rigorous validation of SWB measures set the foundation for SWB being a respected area of research.

Personality and Well-being

Diener and colleagues replicated and explored the relationship between extraversion and SWB, and also differentiated SWB from traits like optimism and self-esteem (Lucas et al., 1996). Researchers theorized that extraverts seek more social interactions, which in turn boost their well-being, but Diener and colleagues found that people relatively higher on extraversion were happier than their less extraverted peers whether they were interacting with others or alone, whether they lived alone or with others, whether they lived in rural or metropolitan areas, and whether they worked in social or nonsocial occupations. This evidence supported the idea that extraverts may not have higher SWB simply because they seek out more social situations, but instead because they have a relatively stronger reward system. In addition, Diener and colleagues found that personality may influence well-being

because it affects what information about our experiences is chronically accessible to people when making evaluations of their lives. Thus, Diener and colleauges sought to not only understand the relationship between personality and SWB, but also the process by which personality acts on SWB.

Income and Well-being

The nuanced relationship between income and well-being at various levels of analysis has been a topic of much scholarly analysis and Diener and colleagues have contributed greatly to the scientific understanding of this phenomenon, elucidating measurement issues within the field. Diener and Biswas-Diener (2002) reviewed the evidence corresponding to the Easterlin Paradox – the hotly debated finding that although income is related to SWB both within and across countries, increases in wealth over time do not correspond to relative increases in SWB – and called for future work to explicate this puzzle. Over the years, researchers debated the presence of the Easterlin Paradox, with some finding evidence supporting its existence and others not. Then, Diener, Tay, and Oishi (2013) produced empirical work that explained many of the divergent findings in the literature. Specifically, in an analysis of 135 countries, they found that life satisfaction does rise and fall with changing GDP, but that happiness, positive affect, and negative affect do not, indicating that the paradox may depend on what type of SWB measure a researcher uses. Furthermore, although many studies use GDP as a measure of wealth, in an analysis of average household income as the wealth indicator, Diener and colleagues (2013) found that all measures of SWB (life satisfaction, happiness, positive affect, and negative affect) showed expected changes with income. Thus, perhaps some of the conflicting findings were due to using a wealth metric (GDP) that did not necessarily trickle down to the average person.

Cultural Influences on Well-being

Diener and colleagues have performed a great deal of research on the predictors and measurement of SWB across and within-cultures, calling for the recognition of cultural-specific and universal norms that affect the experience of emotions and life satisfaction and the relationship between the two. In regard to universal norms, Diener has found that basic and psychological need fulfillment, income, individualism, human rights, environmental health, peace, and societal equality relate to higher SWB across nations (e.g. Tay & Diener, 2011). In regard to cultural-specific norms, Diener and colleagues found that freedom and self-esteem were predictors of SWB in individualistic, but not collectivistic nations, and cultural norms surrounding SWB were predictive of SWB in collectivistic, but not individualistic nations. Similarly, Oishi and Diener (2001) found that independent goal pursuit increased the benefit of goal attainment on SWB in individualistic, but not collectivistic cultures, whereas inderdependent goal pursuit (goals to please parents and friends) increased the benefit of goal attainment in collectivistic, but not individualistic cultures. In addition to large, national surveys of well-being, Diener's interest in culture and well-being has also prompted an interesting collaboration with his son, Robert in which they explore well-being among hard-to-reach populations who are underrepresented in research (e.g. people in the slums of Calcutta)

Hedonic Adaptation

Because of the relatively small amount of the variance in individual differences in SWB accounted for by life circumstances (estimates are usually less than 10%; Diener et al., 1999), the relative stability of SWB over time, and the influences of personality and genetics on SWB, many researchers have suggested that people simply adapt to any hedonically relevant event in their lives, reverting back to a predefined happiness "set-point" and making efforts to improve happiness a fool's errand. With a close review of the literature and empirical contributions, Diener and colleagues were able to demonstrate that people do not adapt to all circumstances and that levels of SWB can change (Diener, Lucas, & Scollon, 2006). Specifically, in one study he noted that although the majority of people remained relatively stable in their SWB over a 5-year period, 24% of people changed significantly. Echoing these results, although on average people tend to adapt to life circumstances, there is wide variability in adaptation among people and events. For example, not everyone adapts to the SWB boost of marriage and, on average, people who have become unemployed or widowed never quite recover from this blow. Furthermore, although researchers note that life circumstances often show a relatively small correlation with SWB, the fact that long-term life circumstances (e.g. the GDP or life expectancy of your country) – and not just recent changes in life circumstances – correlate with SWB at all is evidence of non-adaptation. Thus, as he did on multiple other topics, Diener and his colleagues investigated and uncovered the nuance in the area of hedonic adaptation, revealing that adaptation was not inevitable and SWB can meaningfully change.

Correlates and Outcomes of Well-being

In a highly cited paper, Myers and Diener (1995) answered the question, "Who is happy?" noting the surprising findings that demographic variables such as age, sex, and race show little relationship to SWB. Regardless of these demographic variables, relatively happy people have stronger romantic and other social relationships, are more extraverted and agreeable, and less neurotic than their less happy peers. In one study, participants with the highest levels of happiness again had the strongest relationships and were also more likely to volunteer, but they were slightly less successful in terms of income, education, and political participation than their peers who scored one point lower on SWB (8 or 9 on a 10-point happiness scale). Thus, once moderate levels of happiness are reached, the "best" level of happiness for other positive life outcomes may depend on one's values and goals.

Extensive evidence also supports that not only is SWB related to positive life outcomes, it also precedes and even causes them. In a meta-analysis of 225 studies, Lyubomirsky, King, and Diener (2005) demonstrated the positive effects of SWB on domains such as work, relationships, and health. Given the positive consequences of SWB, Diener (2000) advocated for nations to measure SWB and at least partially evaluate their policies based on how they affected the SWB of their population. The recommendation for a national index of SWB has now been adopted by over 40 nations and researchers are increasingly exploring policy questions related to SWB.

Future Work

On Diener's CV, updated on May 25, 2016, he has 29 scholarly works listed as submitted or in preparation, so Diener's already immense contribution to psychology is still unfolding.

Awards and Service

Diener has received too many awards to list in this entry. A select few are: The Distinguished Scientific Contribution Award for Basic Research from the American Psychological Association, the William James Fellow Award for outstanding contributions to scientific psychology from the Association of Psychological Science, the Distinguished Quality of Life Researcher Award from the International Society of Quality of Life Studies, the Jack Block Award for Distinguished Career Contributions to Personality Research from the Society of Personality and Social Psychology, and various teaching awards. Diener is also past president of three professional organizations, the International Positive Psychology Association, the Society of Personality and Social Psychology, and the International Society for Quality of Life Studies. Additionally, Diener was the founding editor of *Perspectives on Psychological Science* and also served as an editor for the *Journal of Personality and Social Psychology* and the *Journal of Happiness Studies*.

Mentorship and Philanthropy

Living out the prosocial values instilled in him by his parents, Diener uses his time and resources to help others. Although many of Diener's good deeds are likely not a matter of the public record, a few notable accomplishments are. First, Diener has mentored innumerable graduate and undergraduate students both directly as their advisor and teacher and indirectly through his writings and talks, helping them advance their careers. A few years ago, Diener stated that he had published 130 scholarly works with 55 students and former students and he has three students with whom he has published more than 20 papers each (Shige Oishi, Eunkook Suh, and Richard E. Lucas; Diener, 2008). He also notes that he as a high C^2 index for "collaboration" in scholarly works, having 10 scientists with whom he has generated 10 or more publications, and 100 different co-authors overall.

Driven by the belief that knowledge should be made accessible to all, Diener and his wife, Carol, created and financed The Diener Education Fund, a 501(c)(3) non-profit organization with the mission of better serving the needs of students and professors within higher education. Their mission is carried forward in the Noba Project (www.nobaproject.com), a free online platform that provides high-quality, flexibly structured textbooks to students that are written by experts in the field of psychology.

In his autobiography, Diener sends a beautiful message to psychology students that underlines his belief in prioritizing family and good works while still being excellent researchers: "I want to ensure that young, ambitious psychologists do not forget the point that one should not excel at their jobs at the expense of being decent human beings" (Diener, 2008, p. 7).

Erik H. Erikson

Bernardo J. Carducci

Indiana University Southeast

Erik H. Erikson was born on June 15, 1902, near Frankfurt, Germany. His birth was the result of an extramarital affair by his mother. His parents, both Danish, separated shortly before his birth. Wishing to be near her close friends, Erik's mother moved to Karlsruhe, Germany. When Erik was 3 years old, his mother married a local pediatrician, Theodore Homburger, who successfully treated Erik for a childhood disease. Dr. Homburger adopted Erik and gave him his last name. But in what Erik would later call an act of "loving deceit," his parents concealed his adoption for several years. Erik used *Homburger* as his surname until shortly before immigrating to the United States in 1933. He then adopted the surname of *Erikson,* which means "son of Erik."

Although his stepfather was Jewish, Erik was not easily accepted by his Jewish peers because of his tall, blond, Aryan appearance. At the same time, he was rejected by his German peers because they knew he was Jewish. Having to confront being adopted and then being rejected by his peers may have affected Erikson's later concerns with what he was to call the "identity crisis."

Although Erikson was not a particularly good student, he did show some promise in history and art. After graduating from high school and rejecting his stepfather's suggestions to go to medical school, Erik traveled around central Europe for a year. He then returned to Karlsruhe to attend art school. But he quickly became restless again and, until the age of about 25, spent time wandering through Italy and Germany.

In 1927, an old classmate invited Erikson to join him as a Montessori instructor at a private school run by Anna Freud for children whose parents were receiving psychoanalysis from her father. After Erik had worked at the school for a short time, Anna asked him to consider beginning analysis with her and becoming a child analyst himself. During his training with Anna, which lasted from 1927 to 1933, Erik became a very close friend of the Freud family.

Over the next few years, Erikson distinguished himself as a key figure in psychoanalysis through some of his early publications demonstrating how children could become more aware of themselves and their feelings through artistic expression. Thus, with just a high

school education and a diploma as a Montessori teacher, Erikson combined his early talents in art and history to make a unique contribution to psychoanalysis by trying to understand emotional development during childhood.

On April 1, 1930, Erikson married Joan Serson. In 1933, Erikson moved his wife and two sons to Boston, where he became a practicing children's analyst and accepted a position at the Harvard Medical School. At the same time, he began working on a PhD in the psychology program at Harvard. But realizing that he was not suited for formal education, Erikson withdrew a short time later – after failing his first course. In 1936, he accepted a position at the Yale Institute of Human Relations. In 1938, he spent some time studying child-rearing practices among the Sioux Indians in South Dakota.

In 1939, Erikson moved to San Francisco and continued his practice as a children's analyst. In 1942, he became a professor of psychology at the University of California at Berkeley; but he was released in 1950, along with other faculty members, for refusing to sign a loyalty oath. From 1951 to 1960, Erikson lived in Stockbridge, Massachusetts, where he served as a senior staff member at the Austin Riggs Center, a private hospital for disturbed adolescents, and simultaneously held several other part-time faculty appointments at neighboring institutions.

In 1960, he returned to an academic appointment as a lecturer and professor of human development at Harvard. Although he never actually received a college or university degree, Erikson was considered a very strong intellectual by his colleagues and a very popular teacher by his students. His book, *Gandhi's Truth* (Erikson, 1969), won a Pulitzer Prize and the National Book Award in philosophy and religion. Although he retired in 1970, Erikson continued to be a productive researcher and writer. His last book addressed personality growth during the later years of life (Erikson, Erikson, & Kivnick, 1986). Erikson died on May 12, 1994, in Harwich, Massachusetts.

The Nature and Expression of Personality Development

Erickson is best known for the conceptualization of his eight stages of human development. A central feature of Erickson's viewpoint of personality was the development of the ego. Characteristic of ego psychology (Westen & Gabbard, 1999), Erickson proposed the ego as the core of the healthy personality and being responsible for creative thinking, artistic expression, logical reasoning, and joyful expression of emotions. As the motivating source of personality, Erikson proposed that the ego operates in a manner characterized by psychosocial development. Psychosocial development refers to Erikson's belief that the ego develops as it successfully resolves crises that are distinctively social in nature throughout life and are organized into eight developmental stages (Erikson, 1950, 1963). These stages of development are assumed to occur in a specific sequence and build upon each previous stage (Whitbourne, Zuschlag, Elliot, & Waterman, 1992). The sequence is based on the resolution of a particular psychosocial crisis that requires achieving a balance between the needs of the individual (i.e. *psycho-*) and the expectations of society (i.e. *-social*). With the successful resolution of each of the psychosocial crises comes the acquisition of a basic virtue. Basic virtues are attributes of character strengths (e.g. hope) that the ego can use to help when resolving subsequent crises (e.g. pursue future life plans) throughout life.

The Eight Stages of Psychosocial Development

The first psychosocial crisis of trust versus mistrust occurs during the first year of life, which is based on an infant's uncertainty about the world in which he or she lives. To resolve these feelings of uncertainty, the infant looks to the primary caretaker for stability, consistency, familiarity, and continuity in the nature of these experiences. The extent to which the child resolves this sense of uncertainty in the direction of trust will result in the ego acquiring the basic virtue of hope (i.e. faith in the future).

The second psychosocial crisis of autonomy versus shame and doubt appears sometime around the end of the first year of life and continues through the third year. During this period, the child discovers that he or she has many skills (e.g. putting clothes) and abilities (e.g. manipulating toys), which serve to illustrate the child's growing independence and sense of autonomy. As opportunities to demonstrate such skills and abilities arise, the child will begin to develop a sense of mastery over its environment and resolve this crisis in the direction of autonomy and acquire the basic virtue of willpower (i.e. self-confidence) (cf. Kelly, Brownell, & Campbell, 2000).

The third psychosocial crisis of initiative versus guilt occurs during the fourth and fifth years of life. During this period of life, the principal activities involve the child going to school and, for the first time, regularly interacting with a large number of people (e.g. classmates) and exploring interpersonal abilities through play (e.g. deciding what and how to play). As opportunities to exercise these interpersonal skills arise, the child will begin to develop a sense of critical thinking and resolve this crisis in the direction of initiative and acquire the basic virtue of purpose (e.g. self-directed behavior) (cf. Goencue, Mistry, & Mosier, 2000).

The fourth psychosocial crisis of industry versus inferiority occurs in children from the ages 6 through 11. During these years, the child is in school learning to acquire and develop the basic technical skills (e.g. reading, writing, and math) needed to be a productive individual in society. As opportunities to practice these skills arise, the child will begin to develop a sense of how to use these skills in more unique and personal ways (e.g. read and write about favorite activities) and resolve this crisis in the direction of industry and acquire the basic virtue of competency (e.g. sense of self-efficacy).

Ego identity versus role confusion is the fifth psychosocial crisis and lasts from late adolescence to young adulthood (i.e. 18 to 24 years of age). It is during this stage that the individual begins to make the transition into adulthood. Part of this transition involves an initial attempt to establish a sense of ego identity – creating a sense of belonging to a community through friends (e.g. dressing similarly), leisure activities (e.g. gaming club), school (e.g. selecting a college major), and/or work (e.g. job title). Failing to establish a sense of identity within society can lead to what Erikson referred to as role confusion. Such feelings of role uncertainty can create an identity crisis, resulting in the young adult experimenting with different life-style choices (e.g. switching college majors or working at different jobs) in an attempt to identify what he or she enjoys doing or wants to be in the future (Marcia, Waterman, Matteson, Archer, & Orlofsky, 1993). As opportunities to explore different identities and identify with different communities arise, the young adult will begin to develop a sense of belonging and resolve this crisis in the direction of ego identity and acquire the basic virtue of fidelity (e.g. commitment to the beliefs of a group or cause).

Intimacy versus isolation is the sixth psychosocial crisis and spans the period of young and middle adulthood (e.g. late twenties to middle forties). Upon establishing a sense of social identity, the individual is in a better position to begin the task of establishing a meaningful emotional relationship with another person by merging his or her identity with that of another. The individual who is able to integrate his or her identity without having to worry about its loss will resolve this crisis in the direction of intimacy and acquire the basic virtue of love (e.g. the strength and support of a significant other).

Generativity versus stagnation is the seventh psychosocial crisis and corresponds to the period of middle adulthood (e.g. 45 to 65 years of age) during which the individual must realize that beyond just the responsibility of securing his or her own ego development, it is also important to promote the ego development of the next generation of young people by sharing with them one's wisdom and strengths through such activities as parenting, political action, volunteering, and mentoring (cf. Lachman, 2004; Peterson, Smirles, & Wentworth. 1997). Individuals who share their knowledge for the benefit of future generations resolve this crisis in the direction of generativity and acquire the virtue of care (e.g. preparing others to achieve success). While Erikson focused on the notion of generativity as being primarily a midlife issue, examinations of personality characteristics across the lifespan suggest that expressions of conscientiousness appear in young adulthood and continue well into old age (cf. Roberts, Walton, & Viechtbauer, 2006).

Ego integrity versus despair is the last psychosocial crisis and appears in late adulthood (e.g. ranging from about 65 years until death) during which the major developmental task is for the individual to reflect on how his or her ego has developed and review the choices that have been made over the years. An individual who can reflect on the events of the past seven stages with a sense of satisfaction will resolve this crisis in the direction of ego integrity and acquire the basic virtue of wisdom (e.g. inspiring others to live fully).

Applications of Erikson's viewpoint of personality include play therapy to help children deal with emotional trauma and the use of psychobiography to study the personalities of historic figures. Although support for Erikson's stage of personality development exists (cf. McAdams, 1999), critics of Erikson's viewpoint and other developmental-stage theories of personality provide evidence suggesting a lack of discrete stages of adult personality development (Costa & McCrae, 1997).

Hans J. Eysenck

William Revelle

Northwestern University

Hans Juergen Eysenck (born March 4, 1916, Berlin; died 4 September, 1997, London) was one of the most influential personality psychologists of the twentieth century. He was a champion of the scientific approach to psychology in general and to personality in particular. His approach emphasized the integration of basic psychological theory with an experimental approach to the study of individual differences. During his lifetime, his work on behavior genetics, ability, dimensions of personality, and a biological basis to personality went from being disbelieved and controversial to accepted wisdom for the field.

Eysenck was born in Germany to parents both of whom were renowned actors. Because they were frequently on tour, the young Eysenck was raised mainly by his maternal grandmother. After finishing secondary school in 1934, he realized that an academic career would require joining the Nazi party, which he despised. Thus, at age 18, he emigrated to the UK where he did his undergraduate and graduate work at University College of London (UCL). Although most interested in physics, he did not have the necessary course work for the entrance exam for physics and instead pursued an undergraduate degree and subsequent PhD in psychology.

In contrast to the emphasis on experimental psychology at Cambridge, the so called "London School" of psychology emphasized individual differences. UCL had been the home of Charles Spearman and subsequently, Cyril Burt. Both were talented psychometricians heavily influenced by Francis Galton's emphasis on the study of individual differences and the inheritance of personality and ability. Despite some initial language difficulties, Eysenck fitted in very well at UCL and took a first-class undergraduate degree working with Burt before continuing on for his PhD also under Burt's supervision.

Because he was a German national, he was not allowed to join the RAF or other military service and after a brief stint spotting planes for the Air Raid Precaution Services, he took his first appointment after his PhD as a research psychologist at the Mill Hill hospital. Mill Hill was the war time home of the Maudsley Hospital which eventually became the Institute of Psychiatry (IoP) where he spent the rest of his career. Working at the IoP provided him with a golden chance to analyze the data already collected on the numerous

patients. His subjects primarily were soldiers diagnosed with various psychiatric disorders. In contrast to other quantitative personality researchers who used factor analysis of personality ratings or self-reports, Eysenck analyzed behavioral ratings, psychiatric diagnoses, and experimental measures such as those of hypnotic suggestibility. His goal was to marry the best of experimental psychology with the best of psychometrics. His first book, *Dimensions of Personality* (1947) did just that. Based upon his factor analytic results, Eysenck proposed support for a general factor of neurosis with a second, bipolar factor that he considered introversion-extraversion. Even though based upon behavioral measures rather than the traditional psychiatric or clinical ratings or self report inventories, this was a very influential work. He introduced a hierarchical model of high level "types" which could in turn be related to a lower-level factor structure.

Eysenck continued to integrate what he perceived to be the best theories from experimental psychology with his factor analytic results. At the time, experimental psychology was dominated by those concerned with animal and human models of learning. Thus, his subsequent book proposed a biological basis of personality based upon classic learning principles, *The Dynamics of Anxiety and Hysteria* (1957). This volume met with serious criticism, however a subsequent model based upon individual differences in arousal, *The Biological Basis of Personality* (1967) was much better received and continues to be well cited.

The 1967 volume was an ambitious attempt to relate introversion-extraversion to the arousal dimension being studied by experimental psychologists such as Donald Broadbent. Broadbent and his colleagues had noticed the effects various stressors had on task performance. Arousal was seen as the common pathway linking multiple environmental or experimental manipulations (sleep deprivation, caffeine, alcohol, time on task, noise) with cognitive performance. In addition, arousal was related to individual differences in sensory thresholds (including those to pain and noise) and the patterns of findings was similar to those relating individual differences in introversion-extraversion to task performance.

Reflecting the current physiological thinking, the proposed biological mechanisms were the ascending reticular activating system and other parts of the limbic system. Eysenck proposed that introverts had higher resting levels of cortical arousal than did extraverts. With the assumption of an optimal level of arousal, the sensation seeking behavior of extraverts was explained as an attempt to compensate for their lower resting levels. This model, based upon an earlier hypothesis of Wundt, could explain the seemingly paradoxical effect of amphetamines in which the administration of a CNS stimulant leads to calming among hyperactive youth, as well as the tendency of extraverts to smoke and take risky drugs.

The arousal model of Introversion-Extraversion dominated the personality research agenda for the next decade. More importantly, by emphasizing the genetic and biological bases of behavior, Eysenck and his European colleagues kept the study of personality alive while it was under serious attack in the United States.

Eysenck's arousal theory and his later theories influenced and were influenced by Jeffrey Gray whose theories of anxiety and impulsivity reflected individual differences in sensitivities to cues for reward and punishment. As is true of any developing scientific theory, many of Eysenck's ideas have been shown during the subsequent 40 years to be wrong or to be oversimplifications, but his general emphasis upon integrating genetic and

biological principles within the study of individual differences has become the standard model of personality.

Eysenck and Gray took a very different approach to the study of personality than was common in the United States. They both emphasized a "bottom up" approach, going from basic physiological principles and looking for behavioral correlates and consequences. This was in contrast to the lexical approach favored by many in the US. In addition, both Eysenck and Gray emphasized that personality had to have a biological basis which then interacted with social experience to lead to the surface traits observed by others. Eysenck's continued emphasis upon biological and genetic mechanisms were in stark contrast to the general attack on trait theory that swept the US in the 1970s.

Eysenck believed that science was a self-correcting process and that good ideas would supplant weak ones. His 1985 book *Personality and Individual Differences: A Natural Science Approach* (written with his son, Michael) reviewed evidence in favor and opposed to his theories and suggested that personality was indeed moving toward becoming a paradigmatic science.

In cooperation with a number of other individual differences psychologists interested in the study of intelligence, the biological basis of personality, and behavior genetics, Eysenck founded the *International Society for the Study of Individual Differences* and was its first president. In addition, he was the founding editor of the journal *Personality and Individual Differences*. As evidence for his trust in the scientific process, at the first ISSID meeting after he critically reviewed the differences between his and Gray's models of personality he cheerfully announced that Gray would be his successor at the Maudsley.

In addition to his theoretical contributions to the study of personality, Eysenck was also notorious for his strong critique of conventional psychoanalytic therapy and his advocacy for what is now known as behavioral therapy. Although mild mannered interpersonally, his writings could be bitter critiques of the works of others. He wrote not just for the scientific community but also wrote several very influential critiques for the general public. Eysenck did not avoid controversy, and probably thrived on it. From his political analysis of the similarities of the far right and the far left, to his critiques of psychotherapy, to discussions of racial differences in intelligence, he was always willing to take unpopular views.

Going beyond addressing many important theoretical and scientific issues, Eysenck also utilized his empirical approach to studying personality to the application of many significant social issues and concerns. Of particular importance was his research in the study of medicine (cf. Nias, 1997) in which he examined the relationship between personality factors and stress of individuals suffering from lung cancer to identify what he labeled "the cancer-prone type" (p. 55), which he summarized in his book *Smoking, Personality, and Stress: Psychosocial Factors in the Prevention of Cancer and Heart Disease* (Eysenck, 1991). He also addressed the important relationship between personality and crime by proposing a rather novel perspective combining personality factors (i.e. extraversion and psychoticism), biological processes (i.e. low level of cortical arousal), and principles of classical conditioning (i.e. slow rate of learned associations) by suggesting criminality was associated with those individuals who were less likely to develop a conditioned-response "conscience" and associate high levels of unpleasant arousal (e.g. guilt and anxiety) with criminal activities (Eysenck, 1996; Gudjonsson, 1997). In the field of organizational

psychology and the world of work, Eysenck investigated the relationship between personality and occupational preferences and job satisfaction (cf. Furnham, 1997). He also devoted his expertise to study such diverse applications of personality psychology as the relationship between personality factors and sexual attitudes and behaviors (Eysenck, 1976), personality and politics (Eysenck, 1954), and creativity, genius, and madness (Nyborg, 1997), along with efforts to apply principles of scientific investigation to examine critically the claims made by such borderline sciences as graphology, astrology, and parapsychology (Dean, Nias, & French, 1997).

Eysenck demonstrated a most remarkable level of productivity – he published 79 books and 1097 journal articles covering a wide range of topics (Farley, 2000). In recognition of his efforts, Eysenck received many prestigious awards, including the American Psychological Association's (APA) Award for Distinguished Contributions to Science (1988), the APA's Presidential Citation for Outstanding Contributions to Psychology (1994), and the APA Division of Clinical Psychology's Centennial Award for Lifelong Contributions to Clinical Psychology 1996), to name just a few.

Eysenck has had a lasting impact upon the field of personality not just because of the number of students trained at the IoP, nor because of his particular theoretical models, but due to his emphasis upon personality as a paradigm driven scientific endeavor that needs to integrate biological and social mechanisms to understanding individual differences.

David Funder

Sara Fiorot

Rutgers University–Camden

David Funder, Distinguished Professor of Psychology at University of California, Riverside, is a prominent and influential figure in personality psychology. Most notably, his work on accuracy in personality judgment reinvigorated interest and reoriented focus in this research area. In addition, he has conducted important research on delay of gratification, attribution theory, personality development, and the psychological assessment of situations. Funder received his doctorate from Stanford University in 1979 and has gone on to author numerous journal articles and books, including the widely used textbook *The Personality Puzzle* (Funder, 2016). He has received numerous awards recognizing his significant achievements, including the Jack Block Award for Distinguished Research in Personality. He has also received various research grants, including those from the National Institute of Mental Health and the National Science Foundation. In addition to conducting research, Funder is former editor of the *Journal of Research in Personality* and former editor of the *Journal of Personality and Social Psychology*. He is also past president of the Society for Personality and Social Psychology and the Association for Research in Personality. Funder's research has uncovered the processes and variables that make accurate judgments of personality possible. His work has also firmly established personality as a fundamental and persistent driver of human behavior over the life span. In addition, his research on situational construal has begun to fill in gaps in the personality psychology literature by shedding light on the ways in which situations influence behavior and how this might differ across individuals.

Funder has explained that making judgments about others' personalities is an inevitable and essential part of life; without such judgments, people may be unable to explain and predict the behavior of others, let alone get to know them. In a work of seminal importance, he identified the conditions that must be met in order for accurate judgments of personality to become possible (Funder, 1995). In the decades preceding this work, most research emphasized the common errors that plague human judgment and make it largely inaccurate. Funder's work represents a paradigm shift in which the focus is no longer on understanding how human judgment goes wrong but, rather, on understanding what is

necessary for it to go right. This shift was motivated in part by the observation that most of the research conducted on the errors of human judgment was carried out in artificial laboratory environments that separated the cognitive processes involved in judgment from an interpersonal, real-world context. Funder called attention to the fact that the errors identified in the lab may not necessarily manifest in the same way or lead to inaccurate judgments in the real world; in many cases, people are in fact capable of accurately gauging the personalities of those around them (Kenrick & Funder, 1988).

To move beyond the error paradigm and to explain how people are ever able to get an accurate read on others, Funder posited the Realistic Accuracy Model (RAM). The RAM specifies that when accurate personality judgments do occur, the conditions of relevance, availability, detection, and utilization must be met (Funder, 1995). First, to accurately pick up on the fact that someone has a particular personality trait, that person must exhibit some behavior that is *relevant* to the trait of interest. For example, in order to judge whether or not someone is extraverted, the person must behave in ways that reflect extraversion (e.g. be talkative or sociable). Second, trait-relevant behaviors must be made *available* to the judge. It is not enough that someone behaves in an extraverted way; if an accurate assessment of personality is to occur, that person must behave that way in front of the judge. If the extraverted behavior is carried out when the judge is not present, then an accurate personality judgment will not be forthcoming. Third, the trait-relevant behaviors that are made available to the judge must also be *detected* by the judge. Even if extraverted behavior is displayed in front of the judge, it will not ensure an accurate personality judgment if the judge is otherwise distracted or inattentive. The available, trait-relevant behavior must be noticed by the judge. Finally, the trait-relevant behaviors that are available to, and detected by, the judge must be correctly *utilized*. For example, the judge must properly infer that when someone is behaving in a very talkative and sociable manner that that person is likely to be quite extraverted. Funder's model of accurate personality judgment makes it clear that this process is interactive in nature; both the person being judged and the person doing the judging contribute in important ways. This work is of great significance because it clearly articulates the necessary components of accurate personality judgment.

In addition to explaining *how* accurate personality judgments happen, Funder also explains *when* they happen. Elaborating on the four-step process described above, he identified four factors that can affect the probability of these steps leading to an accurate judgment. These factors have to do with the person making the personality judgment (i.e. the judge), the person being judged (i.e. the target), the personal attributes being judged (i.e. traits), and quality and quantity of information on which the judgments are based. The likelihood of an accurate personality judgment is increased by the presence of a good judge, a good target, a good trait, and good information. Funder has found that good judges typically have more knowledge about personality and how it is reflected in behavior. Judges of strong ability who are also motivated to make accurate judgments tend to be more effective. A good target is characterized by transparency and consistency. People who freely express their personalities and behave consistently from situation to situation are more likely to elicit an accurate judgment. Some personality traits are easier to judge and thus can be considered good traits. For instance, it is easier to judge traits that are highly visible to observers (e.g. extraversion) than traits that manifest more as private, internal states (e.g. neuroticism). Finally, good information is a product of high quantity and quality. Accurate

judgments are more likely to ensue if there is ample exposure to someone's personality and if various sources of information are taken into account. Good information ideally consists of what the person says about herself, how she behaves, and what her acquaintances say about her. Funder posits this multifaceted approach to accuracy because it corrects for the errors and biases that arise when relying solely on one of these sources (Funder, 1995).

Funder has been one of the most influential voices in the debate over whether or not personality exists in any meaningful, consequential way (i.e. the person-situation debate) (Kenrick & Funder, 1988). Critics decried the notion that personality has a real and abiding existence, claiming instead that personality is a mere by-product of situational factors that changes depending on context. Critics also argued that the effects of personality on behavior are negligible (Mischel, 1968). However, Funder has effectively refuted such claims by showing that personality traits are, in fact, real and predictive of human behavior. First, the fact that people generally make similar judgments about the personalities of others supports the notion that personality exists as a real, objective phenomenon. For if it was only in the eye of the beholder, there would not be consensus among observers. Second, the fact that these judgments remain fairly consistent between people who know the person in different contexts supports the notion that personality is not entirely dependent on situational factors. Finally, Funder points out that there are indeed associations between personality traits and behaviors that are of the same magnitude as those between situations and behaviors. This supports the notion that personality is an important predictor of human behavior. Funder conceives of personality traits as those characteristic patterns of thought, feeling, and behavior that remain relatively stable over time and across situations (Funder, 1991). His forceful argument, paired with an accumulation of empirical evidence, did much to resurrect this notion of personality and to bolster the entire field of personality psychology.

While Funder does argue that personality is relatively stable across situations and that it can predict behavior, he also acknowledges that it is the interplay of personality and situations that offers the most robust explanation of human behavior. For instance, Funder has shown that having certain personality traits will make one more likely to choose to be in certain situations (e.g. an extreme introvert would be more likely to choose to work at a library than a busy nightclub). Thus, one's quiet behavior at a library might not be entirely due to the situational constraints of that environment, it might also reflect personality traits that led that person to the library to begin with. Situations can make it easier or harder to express certain traits, and a person's traits can alter a situation. Personality traits are more reliable predictors of behavior across time and situations than they are predictors of behavior in specific instances; for this, situational aspects might be more useful (Funder, 2016).

Funder's more recent research has been specifically aimed at understanding how situations influence behavior. He and his colleagues have developed a tool, the Riverside Situational Q-sort (RSQ), to measure the psychologically relevant attributes of situations. This more recent work has also sought to investigate how people from different cultures may construe or perceive the same situation in different ways. The International Situations Project, which includes collaborators from all around the world, is gathering data from various countries to increase understanding of how people from different cultures experience situations and how this might affect their behavior. This cross-cultural research on

situations is groundbreaking, as very few studies of this nature have previously been done in personality psychology. Funder's research will expand to include even more countries and will seek to show how personality interacts with situations to influence behavior across cultures. This type of cross-cultural research aimed at fostering a better understanding of cultural similarities and differences is especially important, as we live in an increasingly interconnected world.

Funder has called psychology to return to its roots of asking interesting and relevant questions that pertain to human existence in the real world (Funder, 2009). His work has been exemplary in answering this call. His research on personality judgment accuracy holds intrinsic interest for anyone seeking to truly know another person, and it may be particularly relevant in clinical and workplace contexts, where personality assessment is especially consequential. By studying the individual components of the personality, situation, and behavior triad and by examining the relations between these, Funder has advanced a more comprehensive understanding of human beings, and he has made significant strides toward answering the most interesting and relevant question of all "Why do people do what they do?"

Lewis R. Goldberg

Gerard Saucier

University of Oregon

Lewis R. Goldberg (b. 1932) is an influential personality psychologist, associated with crucial concepts in the resurgence of this field: the lexical hypothesis, the Big Five, and public-domain measures of personality.

Born in 1932, and growing up in Chicago, Goldberg gained a bachelor's degree in social relations at Harvard University. In obtaining a clinical psychology doctorate from the University of Michigan, he worked with E. Lowell Kelly (1905–1986). Early publications often focused on objective tests considered to have promising clinical applications, but soon his prime focus shifted to personality questionnaires. He was an acting professor at Stanford University from 1958 to 1960, and a professor (initially assistant professor) at the University of Oregon from 1960. He was among the earliest research scientists associated with Oregon Research Institute (ORI), founded in 1960 in Eugene, beginning an association spanning over 55 years. He served as field selection officer in the first few years of the Peace Corps program, and also had Fulbright sabbatical appointments overseas in Turkey and the Netherlands. He served as president of the Society of Multivariate Experimental Psychology (1974–1975) and the Association for Research in Personality (2004–2006), and received lifetime achievement awards from several professional societies.

Goldberg has published over 100 scientific articles. Here emphasized are the most heavily cited and influential ones (Goldberg, 1965, 1968, 1970, 1981, 1982, 1990, 1992, 1993, 1999). This work has involved (a) explications of the rationale for lexical studies of the structure of personality attributes; (b) the Big Five model of personality-attribute structure, its bases in the lexicon, and the optimal way to measure it; (c) the development of a large public-domain item pool as a resource for measuring the full range of personality tendencies; and (d) examinations of the comparative validity of varying assessment methods; as well as (e) earlier work on clinical inference and judgments.

Early rationales for lexical studies had been laid out by Gordon W. Allport (1897–1967) and Raymond B. Cattell (1905–1998), involving a "lexical hypothesis": "Those individual differences that are of the most significance in the daily transactions of persons with each other will eventually become encoded into their language" (Goldberg, 1981, pp. 141–142).

But, unlike Allport and Cattell, Goldberg also completed large-scale empirical projects of the language of personality, leading to numerous widely cited studies. These studies primarily involved American English (e.g. Saucier & Goldberg, 1996), but he collaborated with others in related work involving Dutch, German, Greek, Russian, and Turkish.

From his earliest presentations of the lexical rationale, Goldberg suggested as the prime candidate model a structure of five factors identified in his earlier work with Warren Norman. He coined the term "Big Five" to describe these factors. In cross-cultural applications, most of the six languages mentioned above – as well as several others – did bear out that prediction, with a structure of five fairly recurrent factors emerging from unconstrained exploratory factor analysis. This support in lexical studies proved a crucial component in the eventual ascendance that five-factor models achieved in personality research. These factors were labeled as Conscientiousness, Agreeableness, Emotional Stability, Extraversion, and Intellect/Imagination. From a measurement standpoint, Goldberg's approach has emphasized internal consistency as well as univocality (i.e. items associated unambiguously with one and only one factor). It used initially adjectives drawn directly from the lexicon, but then proceeded to use these as anchors for scales built from short verbal phrases that offer more clarity and specificity than adjectives. Such straightforward, brief, behavior-descriptive items should also prove easier than adjectives to translate, an important cross-cultural consideration.

Goldberg has guided development of an "international personality item pool." Beginning with translations of about 750 items from a smaller scale Dutch project, Goldberg and his team expanded the number of items to over 2,400, all of which were administered over the course of 11 years to a large American community sample. Goldberg has drawn on this pool in creating efficient, relatively brief scales for numerous and widely varying constructs emphasized in current personality inventories.

Several of Goldberg's studies have stressed "comparative validity," that is, the idea that the value of a scale or inventory is most efficiently estimated by placing it in competition with other scales or inventories, in prediction of important outcomes. In this respect, research can crucially function as a sort of "consumers' union" on behalf of the larger audience of test users. His various studies have suggested that rational-intuitive scales, even if constructed by non-experts, outperform external criterion-keyed scales like those prevalent in mid-twentieth-century psychology. This work contributed to a shift in personality psychology's measurement paradigm in the 1970s and 1980s.

Goldberg's studies (like those of his colleague Robyn Dawes) of clinical inference and judgments highlighted the superiority of linear, multivariate, empirical formulas over expert judgments, and the utility of recasting the best aspects of expert judgments as multiple regression formulas. For example, he derived an empirical formula for distinguishing psychotic from neurotic patients based on Minnesota Multiphasic Personality Inventory (MMPI) scale scores (Goldberg, 1965, 1972).

Goldberg has viewed personality primarily in terms of individual differences in aggregate behavioral tendencies. These tendencies are seen as differentiable along five key dimensions. They can be identified empirically via questionnaires (ideally, public-domain measures that are freely available) administered to ordinary people. Goldberg's work tended to put him at odds with several other influential psychologists: Jack Block (1924–2010), who espoused an approach to personality relying more on expert judgment and

psychodynamic insight, rather than on factor analyses of the lexicon as used by ordinary people; Hans J. Eysenck (1916–1997), who advocated for a model of three rather than five personality factors, with a strong predilection for neurophysiological theory as necessarily underpinning any factor; and Paul Costa and Robert R. McCrae, with their non-lexical rationale for a slightly variant set of five factors as represented on a proprietary rather than public-domain personality inventory. The 1990s in particular saw Goldberg involved in stimulating debates on these controversial issues in (as well as outside) publication outlets (e.g. Goldberg & Saucier, 1995).

Noteworthy has been Goldberg's distinctive style in the crafting of scientific contributions. He has read and reviewed widely, serving simultaneously on as many as nine editorial boards. He puts forward a direct and vivacious style in scientific articles. And he has typically circulated manuscripts among several dozen colleagues seeking input before any first submission for publication.

Although Goldberg's main work approached personality assessment with an emphasis on comparative validity, linear models, factor analysis, and the natural language, his scientific interests have ranged wider. He has published work on vocational and avocational interests, trauma and dissociation, demographic characteristics, grading and college learning, and selection of graduate students and Peace Corps personnel, and he has been associated with Sarah Hampson, Jack Digman, and others in longitudinal studies of personality and health from childhood to adulthood (see, e.g. Hampson, Goldberg, Vogt, & Dubanoski, 2006).

Karen Horney

Sarah M. Vanacore

East Carolina University

Karen Horney (1885–1952) was a German neo-Freudian psychoanalyst who challenged Freud's view of women and countered the idea that personality was solely biological and inborn. Her contributions to feminine psychology and her development of the structure of neurosis have had an influence on the interpersonal school of psychoanalysis, and her theories of self-realization influenced humanistic psychologists such as Abraham Maslow and Carl Rogers.

Born in Hamburg to a Norwegian father and Dutch mother, Horney (born Karen Danielsen) was a bright, rebellious child who started cultivating her intellectual talents at a young age. In 1906, she enrolled in the University of Freiburg – one of the only universities which would admit women – and from there transferred to the University of Göttingen and then to the University of Berlin, where she earned her medical degree in 1915. During this time, she met and married Oskar Horney, with whom she would have three daughters but eventually divorce in the 1930s.

While she started as a physician, Horney moved quickly to psychoanalysis. With fellow psychoanalyst Karl Abraham, she founded the Berlin Psychoanalytic Institute in 1920 and continued to be associated with them as a board member and teacher until 1932, at which time she moved to the United States to join the Chicago Psychoanalytic Institute. In 1934, she joined the New York Psychoanalytic Institute and taught at the New School for Social Research. She was expelled from the New York Psychoanalytic Institute in 1941 because her theories deviated from Freud's; she then founded the American Institute for Psychoanalysis and remained its dean until her death in 1952. She also taught at New York Medical College and founded the *American Journal of Psychoanalysis*.

One of Horney's main contributions was her work on feminine psychology, which challenged traditional Freudian psychology's view of women. In "The Flight from Womanhood," (1932) she pointed out that psychoanalysis's phallocentric bias stems from an obvious place: Sigmund Freud was male, and so were the psychoanalysts who came after him (Horney, 1926). She proposed that, contrary to traditional Freudian theories, girls were aware of their genitalia before puberty and that while girls may experience penis envy at a young

age, this longing goes both ways, as young boys often wish for breasts or to be a mother (Horney, 1933). Penis envy at an older age comes from disappointment with the girl's father, leading to the masculinity complex, or a "flight from womanhood" – in effect, the desire not to be female (Balsam, 2013). But, for Horney, this was not inevitable, as a girl could overcome penis envy by identifying with her mother.

Horney traced the "distrust between the sexes" through history and various cultures, comparing the husband-wife relationship to a parent's relationship with a child, one that breeds mistrust and dislike. Likewise, society as a whole simultaneously fears and resents women, forcing them into a position that makes them dependent on men. Horney concluded that the resentment between men and women lay not in women's lack of a penis, but in men's envy of women's ability to produce life; in this, she turned penis envy on its head, positing instead that men have "womb envy" (Horney, 1967). This perhaps encapsulates Horney's most prominent deviation from traditional psychoanalysis: while Freud posited that women were incomplete because they lacked something, a penis, Horney saw women as whole beings who deserved to be seen and discussed on their own terms.

Horney's dissenting views on women, especially during a time in which women were seen as naturally inferior, caused a stir in the psychoanalytic world. She clashed with prominent psychologists of the time, many of whom were concerned about her deviation from Freudian orthodoxy. While Freud never responded to her theories directly, he once called her "able and malicious" and spoke scornfully of female psychoanalysts, saying that they would most likely devalue penis envy in their patients because they could not identify it in themselves (Lunbeck, 2014, p. 184). Horney's insistence on looking at women, and especially female sexuality, as equal to men and male development eventually contributed to her expulsion from the New York Psychoanalytic Institute.

Horney's work was also influential in bringing culture to the forefront of psychoanalysis. Traditional Freudian psychoanalysis viewed everything in terms of instinctual drives, but Horney emphasized cultural and social forces in behavior and psychological characteristics, especially in neurosis (Paris, 1996). Horney recognized the importance of culture in understanding neurosis, as culture defines what is "normal," and neuroses are shaped by and measured against cultural norms (Horney, 1936). She proposed a different definition of neurosis, one that, in her view, could transcend cultural norms by using what she termed "basic anxiety" and "neurotic trends." Even still, Horney's definition was grounded in people's relationships with others, not biological factors. *The Neurotic Personality of Our Time* (1937) described a new structure of neurosis, which Horney saw as stemming from basic anxiety, which in turn stems from family conditions that make a child feel unwanted. Basic anxiety causes people to feel helpless or lost in the world, and they try to fulfill their need for love and acceptance through four "neurotic trends": affection, submissiveness, power, or withdrawal (Horney, 1937; Paris, 1996).

Horney expanded her theories on neurosis in *Self-Analysis* (1942) to include ten neurotic needs: the need for affection; the need for a partner who will take over one's life; the need to restrict one's life within boundaries; the need for power; the need to exploit others; the need for recognition; the need for personal admiration; the need for personal achievement; the need for independence; and the need for perfection (pp. 54–58). Horney saw the need for affection and the need for power as the two driving forces behind neurosis (Paris, 1996). In *Our Inner Conflicts* (1946), she condensed the ten neurotic needs into three trends that

describe how people, in reacting to basic anxiety, interact with others. *Moving toward* people means that one clings to others and seeks to be loved. *Moving away from people* describes a person who does not want to become involved with others. *Moving against people* means that one sees the world as hostile and acts accordingly toward others.

Horney's work on neurosis kept developing. In *Neurosis and Human Growth: The Struggle Toward Self-Realization* (1950), she put forth the idea of the "real self," one that has developed in a healthy way toward self-realization. The real self, or, as Horney called it, the "possible self," is made up of "intrinsic potentialities" that will either flourish or wither, depending on the person and the circumstances (Horney, 1950, p. 17). Horney proposed that a person is like an acorn trying to grow into an oak tree: like the acorn, a person needs the right conditions to flourish. A person needs a warm atmosphere, the freedom to feel and to express feelings, and healthy relationships with others in order to achieve the real self (Horney, 1950; Paris, 1996). Self-realized people know their own minds and feelings. They have a "healthy conscience" (Horney, 1950, p. 131), a different concept from Freud's superego in that the conscience is a "moral agency serving our growth" (p. 131), whereas the superego only tamps down the urges of the id.

Without the conditions that allow self-realization, a person develops a neurotic personality, based on one of the neurotic trends: movement away from, toward, or against people. Instead of self-realization, neurotic people go on a "search for glory" that will allow them to fulfill an "idealized self" (Horney, 1950, p. 31). In Horney's view, although self-realization is difficult to achieve, one can do so under the right circumstances; by contrast, the idealized self is an "impossible self" that will never come to fruition. Failing to achieve the impossible self brings one to the "despised self," because one will always fail to live up to the idealized self's expectations. On the other hand, the "actual self" is the self that exists in any moment, made up of our strengths, weaknesses, failures, and achievements (Paris, 1996). The actual self and the real self may be far or close apart from each other.

There are five ways that neurotic personalities deal with the idealized self. People who move toward people develop compliant personalities whose idealized self is a person is loved and valued (Paris, 1996). To achieve this, they try to become what others need, whether that is self-effacing, or subordinate, or weak. They often suppress aggressive tendencies because they believe that those tendencies would make others not love or value them. On the other end of the spectrum, people who move away from people are detached personalities who desire freedom and independence from others. In essence, they want to be alone and free from others' desires, but Horney points out that freedom from constraints does not mean the freedom to be grow and be the real self (Paris, 1996).

People who move against people are aggressive personalities who fit into three "expansive solutions" (Horney, 1950): narcissistic, perfectionistic, and arrogant-vindictive. Unlike Freud, Horney did not see narcissism as an inherent trait, but rather as a product of one's environment: a gifted child who is pampered and admired may grow up to be a narcissist. Narcissistic people are both convinced of their own greatness and completely insecure; they may boast of their talents without having accomplishments to bolster their claims. Narcissistic people who fail too often, though, may experience a breakdown as reality collides with their idealized selves.

Perfectionistic people have unrealistically high standards, for themselves and others, which Horney attributed to authoritarian parents who made them feel worthless as

children (Paris, 1996). They view themselves as superior to others as they strive for a perfection that they will never achieve. Because they have a legalistic view of the world – that they are fair and just, and so the world should treat them accordingly – failure to achieve a goal or simple bad luck means, for them, that they have failed in their goal of seeking perfection. Perfectionistic people, then, often end up hating themselves. Arrogant-vindictive people are those who may have had a harsh childhood that hardened them to the world. Instead of seeking affection, they actively scorn it, seeking instead to retaliate against those who have or may hurt them. They may be possessive over other people and things, because they both hate and envy others' happiness. They are sadistic, wishing to exploit others for their own purposes, and they see people who express affection and feelings as weak.

Horney's work also influenced other branches of psychology. Abraham Maslow credited her with helping to found humanistic psychology – in fact, she was often invited to the meetings that led to the start of the American Association for Humanistic Psychology – and her work on self-realization influenced Maslow as he created the Hierarchy of Needs (Paris, 1996). Her term "basic anxiety" was also akin to Erik Erikson's "basic mistrust," which Erikson identified as the first stage (trust versus mistrust) of psychosocial development (Paris, 1996). Her theories on neurosis helped to inspire the interpersonal school of psychology and also influenced the DSM-III. Horney's work on neurosis and her mature theory of self-realization, then, influenced not only psychoanalytic theory, but also cultural psychology, interpersonal psychotherapy, and humanistic psychology. Her theories of female development, regardless of her colleagues' derision, forced psychology to begin to see women as complete beings and establish her as a psychologist who anticipated the feminist movements of the twentieth century.

Carl Jung

Bernardo J. Carducci

Indiana University Southeast

Carl Gustav Jung was born in the small Swiss country village of Kesswyl on July 26, 1875. His mother was described by Jung as having emotional problems. His father, a poor but extremely well-read country pastor, introduced his son to the study of Latin at age six. Jung describes his childhood as rather lonely and isolated.

Jung originally wanted to be an archeologist. Because of limited financial resources, he was forced to attend the University of Basel, which did not offer courses in that area. He decided to study medicine because of the promise of greater career alternatives. Intending to be a surgeon, he switched to psychiatry to pursue his interests in dreams, fantasies, the occult, theology, and archeology. Upon graduation, he received an appointment to the Burgholzli Mental Hospital in Zurich where, from 1900 to 1909, he studied the nature of schizophrenia, established an extensive clinical practice, and developed into a world authority on abnormal behavior.

Jung was an early supporter of Freud because of their shared interest in the unconscious. In 1907, Jung traveled to Vienna for his first meeting with Freud where the two talked for 13 consecutive hours! In 1909, Jung traveled with Freud to America where they were to give a series of lectures at Clark University. During this trip, a fissure in their relationship first developed when the two experts were analyzing each other's dreams. During one of their interactions, Freud reacted to Jung in a very condescending manner, as though he (Freud) was the greater authority. This stunned Jung, as he had come to Freud with a world-class reputation, rather than as an intellectual neophyte.

When the International Psychoanalytic Association was formed in 1910, Jung became its first president at the request of Freud. Jung was being groomed to be Freud's heir to the psychoanalytic movement. However, growing theoretical differences, especially over the importance of sexual energy, resulted in Jung's resignation from the group only four years later. The split was bitter and clean. The two men never met or spoke to each other again.

From 1913 to 1917, while experiencing some serious emotional difficulties in his own life and even contemplating suicide, Jung engaged in a monumental effort of self-analysis.

The outcome of this self-analysis produced some of Jung's most original theoretical concepts. After this self-analysis and the recovery from his emotional disturbances, Jung continued his work for over 60 years, establishing himself as one of the most noted psychological thinkers of the twentieth century. For example, Jung studied schizophrenic patients in Switzerland, Navajo Indians in America, native tribes in Africa, and African American patients in Washington, DC. He participated in archeological and anthropological expeditions to explore diverse cultures in Egypt, the Sudan, and India, all into an attempt to verify his theory of personality. He was extremely well read in theology, anthropology, archeology, psychology, ancient texts, the occult, and mythology, as well as psychiatry. He incorporated this diverse knowledge into his theory of personality.

Jung died on June 6, 1961 in Zurich at the age of 85. He was an active and productive researcher and writer his entire life.

Structure of the Mind

Jung's view of the structural nature of personality clearly reflected a redefined, expanded view of the unconscious mind (Campbell, 2008; Jung, 1934/1960). The conscious ego is the center of conscious awareness of the self (Douglas, 2008). The major functions of the conscious ego are to make the individual aware of his or her internal processes (e.g. thoughts or feelings of pain) and the external world (e.g. surrounding noises) through sensations and perceptions at a level of awareness necessary for day-to-day functioning (e.g. a motorist recalls the alternate route for driving into town due to traffic problems ahead). Directly next to the conscious ego and completely below conscious awareness, Jung proposed the personal unconscious region of the mind. The contents of the personal unconscious included all those thoughts, memories, and experiences that were momentarily not being thought about and/or repressed because they were too emotionally threatening. Important elements in the personal unconscious are what Jung described as complexes (Jung, 1934/1960, 1954/1959). A complex is a collection of thoughts, feelings, attitudes, and memories that center around a particular concept. The more elements attached to the complex, the greater its influence on the individual. For example, complexes associated with religion and politics often times tend to have a rather strong influence on the thoughts, feelings, and behaviors of individuals committed to a particular ideology. The influence of the personal unconscious also includes a prospective and compensatory function (Jung, 1916/1969). The prospective function served to help the individual look into the future (e.g. aspirational thinking and setting of goals). The compensatory function of the personal unconscious helps individuals to balance out at an unconscious level the conscious aspects of personality being ignored (e.g. a shy person may dream of being the life of the party).

While the personal unconscious is unique to each individual, the collective unconscious is conceptualized as being transpersonal in nature (Jung, 1917/1966, 1936/1959, 1943/1953, 1945/1953). The transpersonal nature of the collective unconscious reflected Jung's view that there is a region of the unconscious mind containing a collection of general wisdom that is shared by all people, has developed over time, and is passed along from generation to generation across the ages and locations around the world. Contained in the collective

unconscious was a universal set of common thoughts, feelings, behaviors, beliefs, rituals, emotions, experiences, images, and symbols inherited from all of those who ever came before us over time, including animals. The principal function of this collective wisdom is to *predispose* individuals to respond to certain external situations in a given manner to maximize the development of the individual (e.g. a fear of the unknown, search for novelty, desire for social order, and need for the emotional contact with others). Thus, because these predispositions, or hereditary wisdom, are passed along from generation to generation, individuals do not need to start all over again with each new generation, making the task of survival that much easier.

Jung believed all of this inherited universal knowledge was stored in the collective unconscious in the form of archetypes. Archetypes were universal thought patterns and behavior rituals triggered by specific situations and symbols and images representing certain people, ideas, or beliefs. When expressed, these archetypes provide a universal response proven to be adaptive over time and across situations. For example, when groups of humans or animals gather, there seems to be an archetype for creating social order, whether that order is based on strength, knowledge, or ability, and an archetype for language, whether that language is based on bark, words, hand gestures, or music. Over time and across situations, there seems to be archetypes for believing in a higher power (e.g. the sun god, Christ, Buddha, Allah, the stars) to give people hope. There many different representations of the image for a mother archetype (e.g. the Virgin Mary, the Queen Mother, mother nature) which create as sense of caring and comfort. In addition to these general archetypes, Jung proposed very specific archetypes representing core elements of personality. To facilitate the interaction of the sexes, the *animus* is the masculine side of females and the *amina* is the feminine side of males. The *persona* was the tendency for people to develop a certain pattern of behaviors when in public to get along with others, similar to Freud's superego. The *shadow* represents the dark and more primitive side of personality, similar to Freud's id. The *self*, the most important archetype, serves to unite all other aspects of the individual's personality, similar to Freud's ego.

The Dynamics of Personality

Jung (1948/1960) viewed psychic energy as a generalized motivational source designed to help the self achieve a sense of balance. The self achieves a sense of balance within the personality by the ebb and flow of psychic energy among the various aspects of the self according to three basic principles. According to the principle of opposites, for each conscious and/or unconscious reaction within the personality, there is an opposite reaction to it somewhere else within the system (e.g. offset the development of an analytical side of personality at work with the seeking of more creative pursuits during times of leisure). According to the principle of equivalence, any psychic energy taken from one psychic structure (e.g. devotion to friends) is found somewhere else in the system (e.g. cramming for an exam). On the other hand, the principle of entropy states that when one aspect of the personality has a greater amount of psychic energy (e.g. cramming for an exam) the energy will flow back to the weaker aspect to create a sense of balance (e.g. spend extra time with friends after the exam).

Personality Assessment

In a word association test, the individual is given a word and asked to report the first word that comes to mind. Jung (1905/1973, 1907) was the first individual to employ systematically the use of the word association test in the clinical setting (cf. Bennet, 1983). His principal purpose was to use it to help identify the client's problematic complexes. More specifically, by examining what words produced various types of nervous behavior (e.g. stammering and/or changes in respiration rate) in the client, as well as the associations themselves, Jung was able to assess the degree of emotionality of the word associations and uncover their attachment to problematic complexes.

The Myers-Briggs Type Indicator (MBTI) is based on Jung's (1921/1971) type theory concerning differences in the way individuals use perception and judgment as general orientations to their experiences. More specifically, the MBTI illustrates some of the "basic differences in the ways human beings take in information and make decisions" (McCaulley, 2000, p. 117). According to Jung (Campbell, 2008; Jung, 1921/1971), there are two general types of personality attitudes by which individuals orient themselves toward their environment: extraversion and introversion. The extraversion attitude is an outward orientation in which psychic energy is invested in events and objects in the external environment (e.g. prefers group activities). The introverted attitude reflects an inward orientation in which psychic energy is invested in internal and more personal experiences (e.g. prefers to spend time alone). While Jung believed that both types of attitudes are present within each personality, he also thought that in each person one attitude is expressed more at the conscious level than the other (Bennet, 1983). Besides the two basic attitudes of personality, Jung (1921/1971; Bennet, 1983; Campbell, 2008) also proposed the existence of four functions of personality. Each function is characterized by a specific orientation for understanding the events and experiences in the environment.

- The sensation function involves relating to the world through the senses (e.g. To know something, you must be able to hear, smell, see, or feel it.).
- The thinking function refers to the tendency to relate to the world through ideas and intellect (e.g. If something is out there, what is its relation to other things?).
- The feeling function concerns reacting to the world based on the affective quality of one's experiences with it (e.g. Is that something good, valuable, acceptable, harmful, or unpleasant?).
- The intuition function goes beyond all of the other conscious functions and relies on a deeper, more internal sense of understanding (e.g. Although knowing what something is and how it feels, it still does not seem quite right for some strange reason).

As with the two attitude types, Jung assumed that each personality possesses all four functions, but one is often expressed at a more conscious level and predominant at the expense of the others (Ellenberger, 1970). Thus, while a feeling-type person will have to "see it to believe it," an intuitive-type person will know by just having a "gut feeling about it."

The MBTI is an objective self-report inventory designed to measure four dimensions of Jung's typology: Extraversion-Introversion (E-I), Sensation-Intuition (S-N), Thinking-Feeling (T-F), and Judgment-Perception (J-P). Since the descriptions of the E-I, S-N, and T-F dimensions correspond to those given to these terms previously, only the J-P dimension

needs to be defined. Judging types tend to be orderly, systematic, and try to regulate and control their life. On the other hand, perceiving types tend to be curious, open-minded, spontaneous, and try to understand life and adapt to it. The MBTI contains 126 pairs of items, each containing two statements reflecting opposing orientations on the four separate dimensions. Scoring and interpreting the MBTI involves assessing the extent to which the individual's choices for the items are more characteristic of one or the other orientation on the four separate dimensions. Based on the choices made, scores on each of the four dimensions are calculated for the individual. These four scores are then used to classify the individuals into one of 16 possible types (e.g. ISTJ, ISTP, ENFJ, ENTJ, etc.). The extensive use of the MBTI, along with the continued practice of Jungian analytical psychotherapy (Douglas, 2008), represents the contemporary influence of Jung's viewpoint of personality.

Abraham H. Maslow

Bernardo J. Carducci

Indiana University Southeast

Abraham H. Maslow, the first of seven children, was born on April 1, 1908, in a Jewish district of Brooklyn, New York. His parents, who were Russian immigrants, owned a barrel manufacturing company. As the business improved, the Maslows moved their family out of the slums and into a lower-middle class neighborhood. In the new neighborhood, Maslow was the only Jewish boy and the target of much anti-Semitism. As a result, he spent much of his time alone reading books in the library. His relationship with his parents was also somewhat difficult. As a child, Maslow talked about being afraid of his father, and he talked about his mother as probably being schizophrenic. Despite Maslow's strained relationships with his parents, he developed a very close relationship with his mother's brother. He attributes his mental stability to the care and attention he received from his uncle.

After high school, Maslow was persuaded by his father to attend college to study law. Because he was not particularly interested in being a lawyer, Maslow's grades were not very good. He was also troubled by career uncertainty and his love for a woman of whom his parents disapproved. Maslow dealt with these troubled times by leaving New York and enrolling at the University of Wisconsin. Shortly after moving to Wisconsin, Maslow (who was then 20) returned to New York to marry his childhood sweetheart, 19-year-old Bertha Goodman. The newlyweds then returned to Wisconsin. As an indication of the emotional difficulty of his early life, Maslow stated that he really did not start living until he married Bertha and moved to Wisconsin.

Maslow stayed at Wisconsin to earn his BA (1930), MA (1931), and PhD (1934). The educational training he received at Wisconsin emphasized the very rigorous and objective scientific approach to the study of psychology that had become so popular. His doctoral dissertation, which dealt with the sexual behavior of monkeys, was under the direction of the famous experimental psychologist Harry Harlow. Upon completing his PhD degree, Maslow returned to New York and accepted a position at Columbia University as a research assistant to Edwin L. Thorndike, another famous psychologist. He also started teaching at Brooklyn College, where he stayed until 1951. During this time, Maslow began to extend

his early research on the establishment of dominance in monkey colonies to the study of dominance in humans.

Because many of Europe's leading psychologists, psychiatrists, and other intellectuals were settling in New York to escape the Nazis, Maslow was able to meet, interact with, and learn from such personality theorists as Karen Horney and Alfred Adler. Such a stimulating environment would be enough to affect most people's thinking, but Maslow reported that it was the birth of his first child that significantly affected his views. He proclaimed that all of his academic knowledge and training and scientific research with rats and monkeys did little to prepare him for the wonder and mysteries of an infant child. As a result, Maslow shifted his attention away from the study of animals and began to study what he felt were the motivating forces behind personality out of a sincere desire to discover how to improve it.

In 1951, Maslow left Brooklyn College to accept a position at Brandeis University. He remained there until 1969. During that time, Maslow continued to develop and refine his theory on the nature of human motivation, which attracted a considerable amount of recognition.

In 1967, Maslow was elected to the prestigious office of president of the American Psychological Association. He left Brandeis University to become a resident fellow of the Laughlin Charitable Foundation in California, where he began a large-scale study applying his theory of human motivation and the philosophy of humanistic psychology to such topics as politics, economics, religion, and ethics. For all of his efforts, Maslow is considered a major force in the development of the humanistic movement in psychology (Moss, 2001). Having a history of heart trouble, Maslow died of a heart attack on June 8, 1970.

Maslow proposed a viewpoint of the individual that has become known as the third force in psychology, with the psychodynamic emphasis on the unconscious processes and behaviorist emphasis on environmental controls on behavior being the other forces. The emphasis of this third force has been to enhance the dignity of people by studying the internal processes contributing to their self-directed self-enhancement.

The Motivational Nature of Personality

For Maslow, the driving force behind personality was that individuals were constantly being motivated to meet a variety of biological and psychological needs. The meeting of these needs was assumed to operate in a dynamic process rather than in isolation (Maddi, 1996; Reis & Patrick, 1996). The principal objective of these needs is the motivation of the individual to reach a state of self-actualization – attempts by individuals to reach their full potential by using their talents and abilities to the fullest extent while trying to achieve personal growth, satisfaction, and fulfillment.

Maslow organized human needs in a manner designed to promote the achievement of this state of self-actualization by grouping them into deficiency needs and being needs (Maslow, 1970): Deficiency needs are the lower, more basic needs necessary for the survival of the individual, including hunger, thirst, and safety, which serve to motivate the individual to engage in behavior designed to bring about the satisfaction of these needs. Being needs are the higher needs necessary for the achievement of a state of

self-actualization, including those needs reflecting a desire for wisdom and a sense of aesthetics, which serve to motivate individuals to engage in behavior designed to bring about their emotional and cognitive fulfillment. The lower needs are considered to be more potent and to have a greater influence on behavior than the higher needs. As a result of these features, the lower needs are also generally satisfied before the higher needs.

Hierarchy of Needs

Maslow (1970) organized these human needs into five basic groups in a hierarchical fashion. The logic of the hierarchy of needs is that the needs at the lower end of the hierarchy exert more power in that they apply a greater sense of urgency to be satisfied than the needs at the next level. Progressing up the hierarchy of needs results in the individual coming closer to achieving the state of self-actualization. As individuals begin to meet the needs of one category in a consistent and satisfactory manner, efforts are made to begin to meet the needs of other categories higher up in the need hierarchy.

At the bottom of the hierarchy of needs are very powerful physiological needs, which are those directly related to the survival of the individual (e.g. the need for food, water, and sleep). Next are safety needs, which are those directly related to creating a secure and stable environment. Efforts to meet the safety needs include establishing a comfortable place to live and creating a certain degree of routine and predictability in life. Belonging and love needs are directly related to fostering a sense of feeling accepted by others and being part of a community. Efforts to meet these needs include establishing meaningful relationships through family, friends, one's neighborhood, religious groups, or professional organizations. Esteem needs are characterized by the desire to have the respect of others and a sense of self-respect. Efforts to meet these needs might include securing the respect of others by taking a leadership role in an organization at school or running for office in the community. Self-actualization needs are characterized by the desire for individuals to develop their abilities to their fullest potential. Efforts to meet these needs involve individuals being aware of, and accepting, their own abilities and potentials and, based on this sense of self-awareness, pushing themselves to their maximum limits to meet personal and situational challenges throughout life. Thus, he believed striving for self-actualization was a life-long process of all individuals in their quest to seek personal enhancement and self-improvement. For Maslow, the uniqueness of expression of personality we see in different people is the special way each individual elects to meet their needs in a consistent manner over time and across situations.

Maslow's views have been applied to a wide variety of areas, including psychotherapy (Boorstein, 2000), religion and spirituality (Elkins, 2001; Maslow, 1976), athletic performance (Privette, 2001) and consumer behavior and marketing (Hawkins, Mothersbaugh, & Best, 2007). Although these applications of Maslow's viewpoint provide some support for its utility, criticisms of this perspective include the use of many concepts and processes to describe the operation and expression of personality that are difficult to explain (e.g. Upon what basis did Maslow select the five need categories?) and test objectively (e.g. What is the measure to assess the extent to which an individual is making progress toward self-actualization if it is different for each individual?)

Dan P. McAdams is a personality psychologist known for contributions to the study of personality theory, assessment, generativity, adult development, self and culture, political psychology, and perhaps most, pioneering the narrative study of lives and the theory of narrative identity. He is also well known as an integrative thinker, developing a three-domain framework for understanding personality, encompassing dispositional traits, characteristic adaptations, and narrative identity.

McAdams is the Henry Wade Rogers Professor of Psychology and a Professor of Human Development and Social Policy (HDSP) at Northwestern University. He has served multiple terms as Chair of the Psychology Department, HDSP, and the Program in Counseling Psychology. He previously held the rotating Charles Deering McCormick Professor of Teaching Excellence Chair at Northwestern University (1995–1998). He is the recipient of many awards and recognitions, including the Henry A. Murray Award (1989) and the Jack Block Award (2012) from the Society for Personality and Social Psychology, the William James Book Award (2006) from the American Psychological Association, the Theodore Sarbin Award (2012) from the Division of Theoretical and Philosophical Psychology of the APA, an award for teaching excellence from the Undergraduate Psychology Association at Northwestern University, and two honorary doctorates. He is the author of nearly 300 peer-reviewed journal articles and scholarly books, many of which are highlighted here. His work has been covered by numerous popular media outlets, including *The New York Times*, *The Atlantic*, *The Wall Street Journal*, *The New Yorker*, *The Washington Post*, National Public Radio, and *The Chronicle of Higher Education*. McAdams served as a founding member of the Association for Research in Personality and its President (2016–2017). His research has been supported by two decade-long grants from the Foley Family Foundation, as well as from the John Templeton Foundation. He has mentored numerous graduate students, postdoctoral fellows, as well as many undergraduates.

McAdams was born in Lynwood, California on February 7, 1954, but moved as an infant to his parents' hometown of Gary, Indiana, where he lived until graduating from high school. As a child, McAdams felt unfulfilled by his options in Gary. He played baseball and read voraciously. He worked jobs in the local steel mills and in his father's car dealership. His parents divorced when he was in grade school and McAdams and his two siblings were raised by their mother, a telephone operator. He knew early on that college would offer him access to a different world, and he was right. He enrolled at nearby Valparaiso University, where he was admitted to the Honors College which introduced him to the Western canon. McAdams double-majored in psychology and the humanities, an intellectual pairing that would inform his intellectual life throughout his career. McAdams credits his introduction to Freud for stimulating his interest in human behavior and the relationship between mind and society. He has written that Freud, along with other figures like Aristotle, Cervantes, Dostoevsky, Kierkegaard, Sartre, and Buber were "like characters in my life" during those years. It was also during college that McAdams met Rebecca R. Pallmeyer, the women who would ultimately become his wife. The two graduated from Valparaiso in 1976 and wed in 1977. Pallmeyer is now Chief Judge of the United States District Court for the Northern District of Illinois (nominated by President Bill Clinton in 1997 and commissioned in 1998).

In 1976, McAdams enrolled in the PhD program in Psychology and Social Relations at Harvard University. He studied among several leaders in the fields of psychology and human development, including Professors Dante Cichetti, Carol Gilligan, George Goethals, Jerome Kagan, David C. McClelland, and Sheldon White. McAdams was mentored primarily by Goethals and McClelland. Through his work with Goethals, he continued to pursue and refine his interests in psychoanalysis and in lifespan human development. McClelland was a key figure in the study of human motivation and famous for developing assessments of basic human needs, including the needs for power, achievement, and affiliation. McAdams's dissertation and early works (e.g. McAdams, 1980; McAdams & Powers, 1981) reconceptualized McClelland's affiliation motive as *intimacy motivation* – defined as a recurrent preference or readiness for experiences of warm, close, and communicative interaction with others – and developed valid ways of assessing this construct by using the Thematic Apperception Test (TAT).

After graduating in 1979, McAdams taught as a Visiting Lecturer at St. Olaf College (Northfield, MN) and at the University of Minnesota for one year before being hired in 1980 as an Assistant Professor of Psychology at Loyola University of Chicago. While at Loyola, McAdams and Pallmeyer welcomed their two daughters.

In the 1980s, McAdams continued his pioneering work on intimacy motivation (assessed though the content analysis of TAT stories) with a series of innovative studies. For example, McAdams (1982) showed that intimacy motivation predicted higher levels of intimacy themes in positive autobiographical memories. In an experience sampling study assessing feelings, thoughts, and behaviors in daily life, intimacy motivation was positively associated with a variety of indicators of warm interpersonal relations (McAdams & Constantian, 1983). When asked to recount interactions with friends, people with higher levels of intimacy motivation reported more close, caring, and open communication styles (McAdams, Healy, & Krause, 1984).

It was also during the 1980s that he developed his influential life-story model of identity (McAdams, 1985). Inspired by William James's distinction between the *I* (self-as-subject)

and the *Me* (self-as-object), McAdams theorized that the *I* arranges the *Me* into a configuration – the life-story – that provides a person with a sense of unity, coherence, and purpose. A person's life-story, like all good stories, contains characters ("imagoes"), themes (e.g. agency/power, communion/intimacy), important scenes (nuclear episodes, self-defining memories), and varies in structure (simple/complex). McAdams integrated his motivational research based on the TAT with thematic coding of life stories to find links between intimacy motivation and life-story themes of affiliation, as well as links between power motivation and life-story themes of agency.

Both continuity and change are evident in the next chapter of McAdams's career. The 1980s closed with his transition from the department of psychology at Loyola University of Chicago to the department of HDSP at Northwestern University. It was at this latter institution that McAdams achieved several milestones. Among them is the publication of his 1993 book, *The Stories we Live By: Personal Myths and the Making of the Self* and his highly influential article, *What do we Know when we Know a Person?* (McAdams, 1995). In these publications, McAdams began to more thoroughly speculate on the nature of life stories from a lifespan development perspective. Furthermore, in the latter publication, McAdams introduced his multilevel conception of personality in which constructs are placed within one of three conceptual and empirical levels: personality traits (broad patterns of affect, cognition, and behavior), characteristic adaptations (constructs couched within developmental and situational spaces), and life stories. The impact that this writing has had on the field of personality psychology – and psychology more broadly – is palpable.

At and around this time, McAdams (1993, 1995) articulated several features of life stories that guided later empirical projects. His professional affiliation also shifted slightly, as he came to adopt a joint position at HDSP and the department of psychology at Northwestern. Some of the concepts he introduced in relation to life stories have become cornerstones of narrative research (e.g. agency, communion), whereas others have not received as much research attention (e.g. imagoes). It is in the mid-1990s that we begin to see the emergence of an empirical field of study focused on life stories. Given that McAdams was heavily influenced by the writing of Erik Erikson and was now himself a parent, perhaps his evolving interest in generativity, broadly defined as a care and concern for the well-being of the next generation, could have been anticipated. His work in this area led to several contributions. Notably, his article on the life stories of highly generative individuals (McAdams, Diamond, de St. Aubin, & Mansfield, 1997) was the first empirical paper to appear in the flagship journal of social and personality psychology (cf. the *Journal of Personality and Social Psychology*) that focused on the analysis of life stories.

One of the major findings emerging from this work was that highly generative individuals tended to narrate the major autobiographical events from their lives using redemptive imagery (wherein a negative beginning gives way to a positive ending; see also, McAdams, Josselson, & Lieblich, 2001). It was shortly thereafter that he published, *The Redemptive Self: Stories Americans Live By* (McAdams 2006). A more nuanced understanding of life stories is evident in this book, as McAdams worked to marry an appreciation of the highly personal and highly cultural nature of the stories we live by. For these and other readings, this book received the 2006 William James Award from the American Psychological Association, which is awarded to the best general-interest book published in the applicable year.

That same year also saw the publication of one McAdams' most highly cited articles (co-written with Jennifer Pals, now Lilgendahl), "The New Big Five," a piece in the *American Psychologist*, in which he further developed his three-level approach to the human person by adding evolutionary and cultural levels of analysis (McAdams and Pals, 2006). This work displays one of his major contributions to personality science: theory building that synthesizes findings from disparate research traditions thereby calling personality researchers to think beyond their silos. Running through this article, and many others from this time period, is McAdam's conviction that the human person is the proper subject of study for personality science. McAdams marshaled a broad array of conceptual and methodological tools to this end. In high-profile publications from 2010 to 2013, McAdams further refined his theory of the human person by developing the model of the self as actor, agent, and author. This line of work culminated in his 2015 book, *The Art and Science of Personality Development*, which broke new theoretical ground as a contemporary account combining personality and developmental science. Throughout this time period, McAdams was prolific in publishing empirical research on topics ranging from the whole person, political psychology, well-being, generativity, psychotherapy narratives, motivation, and narrative research methods. The fruitfulness of his approach is seen both in this empirical output but also in the large number of students, collaborators, and researchers, both in the United States and internationally, who employed his theoretical and methodological innovations for the advancement of narrative research, personality science, and allied fields.

With the publication of *George W. Bush and the Redemptive Dream* in 2011, McAdams pushed the field of personality psychology to return to one of its original endeavors, psychobiography, the aim of using empirically grounded principles to understand the personality of a single individual. In the following years, McAdams would use state-of-the-science approaches to describe the lives of multiple public figures. Most notably, in the pitch of the US presidential election season in 2016, McAdams wrote, "The Mind of Donald Trump," a cover story for *The Atlantic*. With this piece, McAdams showed how personality science helps explain figures that shape current politics. McAdams presents a more complete psychobiography with the publication of The Strange Case of Donald J. Trump in 2020.

In a personal essay written in 2005, McAdams referred to himself as "a psychologist without a country." He described his career-long division between the empirical social sciences and the humanities, a tension which renders him fluent in the dialects and customs of both fields, and no single refuge to call his home. Over the course of his academic career, he has made both locales his primary residence for periods of time, but continues to struggle with the challenges of, and to reap the benefits of, "dual citizenship." Yet this unique bicultural academic identity may be the source of many of McAdams' greatest contributions. Indeed, pursuing problems as complex and significant as the narrative nature of identity demands epistemological and methodological flexibility.

Walter Mischel

Anjana Balakrishnan

Western University

Background

Walter Mischel was born on February 22, 1930 in Vienna, Austria and immigrated to the United States during childhood. He earned a Bachelor's degree in 1951 from New York University and a Master's degree in 1953 from the City College of New York followed by his doctorate in Clinical Psychology in 1956 from Ohio State University. He then commenced his academic career at the University of Colorado, and subsequently held university positions at Harvard and Stanford. From 1983 he had held the role of professor at Columbia University. He had over 200 publications which include peer-reviewed journal articles, book chapters, book reviews, encyclopedia entries, and textbooks. Some prominent positions he held include the following: President for the Association of Personality (2002–2003), Editor of the *Psychological Review* (2000–2004), Fellow of the National Academy of Science (since 2004), President of the Association for Psychological Science (2008–2009), Editorial Board Member for Social, Cognitive, and Affective Neuroscience (since 2005). Mischel died in New York on September 12th, 2018.

The Marshmallow Test, Hot-vs-cool Systems, and Current Relevance of this Research

The 1960s mark the decade in which Mischel and his collaborators began their research to determine the factors that were facilitative and deterrent for *self-control* and their long-term implications. Self-control was defined as the ability to delay gratification (i.e. to choose to wait for a larger reward instead of succumbing to get a small instant reward; Mischel, Shoda, and Rodriguez, 1989). The name "Marshmallow Test" was adopted to describe this line of research because in early research on delay of gratification, the research design involved preschool children choosing whether they would wait to get two marshmallows (or an alternate desirable food reward) or would lose patience and settle

for a single marshmallow which the experimenter would offer whenever requested and without delay (e.g. Mischel & Ebbesen, 1970). A series of studies on this topic led to several insightful findings as outlined in Mischel et al. (1989).

As a starting point, it was seen that some preschoolers found it easier than others to delay gratification to receive a larger reward (i.e. without being given support on how to do so). The implication of such variation is that it indicated that the capacity for delaying gratification could be considered as a personality characteristic. However, the same program of research also found that children when given instruction on ways in which gratification could be delayed were successful at delaying. Such a finding showed that delay of gratification can also be viewed as a malleable psychological process that can be engaged in. Also, in conditions where children could view the reward or focus on its pleasing qualities (e.g. how delicious the marshmallow would taste), the capacity to wait was hampered. In contrast, it was observed that children can prolong wait times in conditions where there is a means for distraction or via construing the reward in an abstract manner (e.g. viewing the marshmallow as a different object that is less appetitive). Importantly, a practically-relevant finding from this research is that self-imposition of a delay by a child showed links to long-term positive outcomes such as higher SAT scores and being perceived by parents as better adjusted and competent.

To explain the nuances that influence how long people wait for gratification, a *hot-cool system framework* was put forward by Metcalfe and Mischel (1999). Per this framework, individuals have two cognitive systems that play a role in information-processing and which in turn can influence how decisions are made. The two systems are hot and cool, and when considering how they vary, the distinction of impulsivity versus rationality can be invoked. The *"hot" system* is emotion-centric and is triggered by stimuli such that people may respond in a quick and reflex-based manner. In contrast, the *"cool" system* is focused on cognition and involves self-control in that people respond to stimuli in a manner that is slower and more strategic. Applied to the Marshmallow Test, the hot system directs a child to want the marshmallow sooner, but the cool system enables the child to wait for a better outcome. The paper goes on to describe how waiting can occur if individuals train themselves to "cool down" hot stimuli (e.g. a marshmallow) using methods such as distraction from the stimuli, blocking the stimuli from view, or thinking about informational rather than emotional features of the stimuli.

The Marshmallow Test represents a classic study in psychology, but its principles and design have been applied and expanded upon in current research. Casey et al. (2011) have documented the temporal stability of the capacity for delaying gratification, and their findings have shown that even after four decades, those who found gratification delay difficult as a child remained less effective at gratifying delay as adults. Furthermore, research by Watts, Duncan, & Quan (2018) attempted to conceptually replicate longitudinal research using the Marshmallow Test. Their aim was to enhance generalizability and to address some limitations of the original research (e.g. sample size constraints and confounding variables not being adjusted/controlled for). In line with earlier findings by Mischel and colleagues, these researchers also discovered a positive link between being able to delay gratification at a young age with achievement when in adolescence. However, in their sample when control variables (e.g. background characteristics, cognitive skills, behavioral skills, etc.) were included in the analysis, the gratification delay and achievement link reduced

greatly, and in some cases failed to be significant. It is noteworthy that Watts et al. (2018) acknowledged in their discussion that the possibility of control factors driving the positive gratification-achievement link is one that is not inconsistent with ideas presented in the study they chose to replicate by Shoda, Mischel, and Peake (1990).

The Person-Situation Debate and the Cognitive-Affective Personality System (CAPS)

Just as many people associate research on delay of gratification to Walter Mischel, so too is he renowned for his trailblazing publication *Personality and Assessment* (Mischel, 1968). In this book, a major premise was the acknowledgment of the inadequacy of personality variables at effectively predicting cross-situational behavior. In a follow-up article several decades later, Mischel (2009) clarified that the aims of the book were not only to identify problems and limitations concerning methodology and theoretical assumptions in personality psychology, but also to put forward the notion that finding consistency in behavior across situations can be enhanced when factors other than personality are also considered in prediction. Despite these aims, the book facilitated the *person-situation debate* wherein scholars in personality and social psychology disagreed as to whether attributes of personality or situational variables were better predictors of behavior.

Subsequent to the controversy created by this volume, Mischel and Shoda (1995) published a paper entitled *A Cognitive-Affective System Theory of Personality: Reconceptualizing Situations, Dispositions, Dynamics, and Invariance in Personality Structure*. In this paper, research was presented with the intent of resolving the ongoing debate by providing a testable theoretically sound model on how behavior is multiply determined. In this CAPS model, the key components are fivefold and collectively are referred to as *cognitive-affective units (CAUs)*. Briefly described, these units are *encodings* (i.e. ways in which pre-existing or novel information is stored in the mind), *expectancies and beliefs* (i.e. what individuals have internalized and believe about themselves, their outcomes, and their surroundings which in turn shapes their responses), *affect* (i.e. feelings and emotions that feed-forward to affect behaviors and thoughts across situations), *goals* (i.e. outcomes that individuals work toward or are motivated by) and *competencies and self-regulatory plans* (i.e. actions individuals have the capacity to engage in along with the approaches people take to achieve desired outcomes). As a testament to the utility of CAPS, this framework is still being adopted and adapted by scholars as a means of answering key research questions within the field of personality psychology. To illustrate, Armstrong, van der Lingen, Lourens, and Chen (2018) sought to discover the cognitive-affective units that contribute to individuals engaging in behaviors that demonstrate *grit* (i.e. goal commitment despite adversity).

The CAPS system hypothesizes that individuals possess different personality characteristics and encounter a number of situations in their lives, and their choice of behavior will depend on which cognitive-affective units get activated. In this sense, the person-situation debate is irrelevant given that both innate qualities of a person and extrinsic situational factors in conjunction shape the activation of CAUs and predict behavior. This model also clarifies a concern brought up in the person-situation debate regarding personality stability (i.e. variable behavior across situations is construed as being at odds with the idea of stable personality). To address

this issue, the argument made in the paper, based on previous research studies, is that individuals have *if...then... behavioral signatures of personality* based on CAUs activated in different situations, and these reflect a form of stable individual difference. To expand, if...then...signatures are the idea that a person engages in Action A in Situation X, but does action B in situation Y (i.e. different situations are linked with different behavioral responses). Evidence has shown that just as individuals show consistency in mean levels of a trait (e.g. being seen as high on neuroticism), so too is there a tendency to act in specific ways in specific situations (e.g. always performing action B in situation Y).

Acknowledgments and Awards

Walter Mischel held the title of the Niven Professor of Humane Letters in Psychology at Columbia University. Throughout his career, he received a number of awards for his scientific contributions. In 2005, he received the Jack Block award for Distinguished Contributions to Personality Psychology. Later, in 2009, he was the recipient of the Grawemeyer Award for his research on self-control and delay of gratification. Recently, in 2015, he and his collaborators received the Golden Goose Award from the American Psychological Association for their longitudinal work on self-discipline. Additionally, he was widely recognized by both the scientific and lay community as a highly influential twentieth-century psychologist.

Conclusion

Professor Walter Mischel was a reputed scholar whose research had garnered the interest of both the scientific community and the general public. His scholarly writings have helped answer the following questions among others: How, when, and why do people engage in delaying gratification? How do both personality and the situation play a meaningful role in behavioral prediction? His works have held the test of time, are still cited today, and have offered a foundation for scientific growth in the field of personality psychology.

Carl Rogers

Lucinda Woodward

Indiana University Southeast

Experience is, for me, the highest authority. The touchstone of validity is my own experience. No other person's ideas, and none of my own ideas, are as authoritative as my experience. It is to experience that I must return again and again, to discover a closer approximation to truth as it is in the process of becoming in me. (Carl Rogers, *On Becoming a Person*)

Rogerian Therapy

Carl Ransom Rogers (American psychologist, born: January 8, 1902 – died: February 4, 1987) has been dubbed in psychology the father of "client-centered therapy," later termed "person-centered therapy." This influential theory of personality, and the resulting therapeutic approach, is founded firmly in the phenomenal field of humanism advocated by eminent researchers such as Combs, Snygg, and Maslow. It is based on the belief that persons should be free to choose their values, life choices and growth orientation.

Unlike traditional psychoanalytic approaches to therapy, or the contemporary behaviorist movement, client-centered therapy examined the wholistic picture of the individual with the therapeutic goal to help the client reach full potential as a person. This psychological perspective deviated from earlier practices in that symptoms, and resulting diagnoses, were no longer the primary focus of treatment. Rogers believed that psychopathology arose from poor self-concept developed from negative messages communicated to us in early development. These negative messages instill "conditions of worth" that can never be achieved, resulting in "lack of congruence" between the real self that we wish to be and the ideal self we strive to become. His therapy communicated what he termed, "unconditional positive regard" for the client through supportive statements, lack of judgment – regardless of the nature of the client experience – and encouragement for the development of the self (Rogers, 1959).

According to Rogers, a fully functioning person manifested several key traits (Rogers, 1961):

1) Openness to experience
2) Mindfulness to the moment
3) Trust in self
4) The ability to make choices and take responsibility for them
5) A creative and non-conformist lifestyle
6) Reliability
7) A full life that encompasses a rich spectrum of emotions

Career Accomplishments

Both a prolific researcher and clinician, Rogers continues to stand out among his humanistic peers for his advocacy of empirically supported therapies. He authored numerous journal articles and 19 books, among the most recognized of which are *Client-Centered Therapy* (1951), *On Becoming a Person* (1961), *Person to Person: The Problem of Being Human* (1967) and *A Way of Being* (1980). Recognized for his accomplishments as both a researcher and practitioner, Rogers was nominated as the president of the American Psychological Association in 1947 and was later honored for his pioneering research with the APA Award for Distinguished Scientific Contributions in 1956. After an illustrious academic career, he went on to become the co-founder of the Center for Studies of the Person where he conducted research and performed therapy until his death in 1987. Prior to his death, he was nominated for the Nobel Peace Prize for his work to unite the Catholics and Protestants in Northern Ireland and to abolish Apartheid in South Africa (Cohen, 1997).

Early Life

Carl Rogers was the fourth of six children born to his upper middle-class family in Oak Park, Illinois. His father, Walter Rogers, was a college-educated civil engineer and his mother, Julia, was a housewife. Both of his parents were profoundly religions and Rogers was raised in a fundamentalist Protestant tradition. Perhaps born of this religious conservatism, Rogers reported that his parents, although loving, were also quite controlling of their children's behavior (Thorne, 1992). He noted that he suspected that if they had known his true thoughts, his parents would not have approved of him. In retrospect, Rogers speculated this upbringing may have led him to develop a deep need for acceptance and positive regard at an early age.

Precocious even as a young child, Rogers demonstrated such high intellect that he started school in the second grade. Records show him to have been a high achiever throughout his early education. When he was 12, his parents moved to rural Illinois where he determined to pursue a career in agriculture. During his undergraduate career at the University of Wisconsin, however, he participated in a fateful six-month trip to Beijing, China where he was exposed to great human exploitation. Following his return to the United States, he developed a stomach ulcer and was hospitalized for several weeks.

Because of this experience, he reconsidered his career objectives and switched his major to History and graduated in 1924 with the intent to attend theological seminary to become a minister (Thorne, 1992).

Rogers reportedly soon became disenfranchised by the structure of his curriculum at the Union Theological Seminary in New York, which was at the time renowned as the most liberal of theological institutes. While there, however, he was responsible for organizing a revolutionary new seminar format that had no instructor or course topic and was organized exclusively around the students' questions. He later attributed this experience to the development of his own "person-centered" therapeutic approach (Demorest, 2004). Following a formative class in psychology taken with Letta Stetter Hollingworth at Columbia University, he again shifted career goals to pursue his doctorate in Psychology at Columbia, graduating in 1931.

Career

His work with the Society for the Prevention of Cruelty to Children, following his doctoral training, later went on to shape his non-directive interventions in three ways. The first instance was following his unsuccessful work with a young man who had both a penchant for starting fires and for masturbating. From a strict Freudian perspective, Rogers initially treated the young man for his unsatisfied sexual urges and released him. When the teen was promptly caught setting another fire, however, Rogers was struck by the realization that even authorities such as Freud could be wrong. His second insight came when he reviewed a parent interview conducted by a caseworker which presented as a legalistic documentation of guilt rather than an insightful interpretation of events and motives. He later surmised that such a line of questioning could be of no help to the client. His third revelation came following the failed family therapy with a distressed mother and son. Following multiple attempts to guide the mother to insights into her rejection of her own son, Rogers finally became aware that the core problem was not with the mother, but rather the relationship between the parents. This led Rogers to the conviction that perhaps the client, and not the therapist, is the best guide to therapeutic goals and outcomes (Demorest, 2004).

Rogers worked as a child psychologist for 13 years prior to assuming his first academic position at Ohio State University. It was during this time that he realized that he had a novel approach to offer the field of psychology. First introduced during an invited talk at the University of Minnesota, his revolutionary critique of traditional methods of psychotherapy, framed in the lecture titled, "Newer Concepts in Psychotherapy," launched a furor of controversy. This hostile response to his ideas led him to begin work on his first book, *Counseling and Psychotherapy: Newer Concepts in Practice* (Rogers, 1942).

It was at Ohio State that Rogers set out to demonstrate the effectiveness of his non-directive therapeutic approach through an extensive case study – the first of its kind to entail a complete audio account of verbatim client-therapist contacts – for Herbert Bryan. The client in this exemplar was a sexually conflicted young man who had internalized his parents' negative messages about himself and his sexuality. As the transcript of the eight sessions with Bryan demonstrate, using a non-directive and supportive approach, the client was

encouraged to both diagnose his own problem and prescribe his own treatment throughout the therapeutic process (Demorest, 2004).

Rogers' formal launch of client-centered therapy was in 1959 in a paper entitled, "A Theory of Therapy, Personality, and Interpersonal Relationships, as Developed in the Client-Centered Framework" (Rogers, 1959). At the center of this theory was his belief in the self-actualizing potential of all humans – the innate drive to become fully functioning persons.

He later went on to establish a counseling center at the University of Chicago where he worked for 12 years. Surrounded by a dynamic group of forward-thinking colleagues, he often described this time as some of his most creative and productive service up to that point. This period was marred only by his own mental crisis following two years of unsuccessful therapy with a deeply disturbed female client (Demorest, 2004). Rogers eventually left with the intention to take a position at the University of Wisconsin where he felt that he could have a greater impact on the field. This move proved in many ways, a disaster. Conflicts within the psychology program prompted Rogers to resign his position prior to moving to the Western Behavioral Studies Institute in La Jolla, California. Here, Rogers joined the free-spirited encounter movement and began working with more normal populations. His final career move in 1968 led him to join fellow humanistic colleagues in founding the Center for Studies of the Person (Thorne, 1992). He remained there for another 20 years actively engaging in therapy, performing research, and writing until the end of his life.

The Gloria Films

Rogers was often invited to compare his therapeutic orientation to that of other theorists and his work in this regard is featured in the book *Three Psychologies: Perspectives from Freud, Skinner, and Rogers* (Nye, 1996). But perhaps the most famous contrast in orientations was featured in a film entitled *Three Approaches to Psychotherapy I, II, and III* directed by Everett L. Shostrom. Designed as a psychotherapy training video that was released in 1965, Carl Rogers, Albert Ellis, and Frederick Perls (representatives of three prominent psychotherapeutic orientations of the time) demonstrated their therapeutic techniques on a young female client named Gloria. According to most accounts, Rogers gave a flawless performance. In fact, as the session began to wind down Gloria said, "Gee, I'd like you for my father." And Rogers replied, "You look to me like a pretty nice daughter." This moving moment became an ideal billboard advertisement for his own theory. Moments after the session with Rogers, Gloria announced that, "All in all I feel good about this interview." And yet, after experiencing all three sessions, Gloria indicated that she gained the most from her more adversarial work with Perls (Weinrach, 1990). The debate as to why Gloria made this determination remains unanswered.

Learner-centered Teaching

Later in his life, Rogers extended his person-centered orientation to other applications such as political mediation and even education. The Learner-Centered Model of teaching resembles classical person-centered approach in its interpersonal orientation. Published posthumously, Rogers and Harold Lyon collaborated on a book, *On Becoming an Effective*

Teacher – Person-centered Teaching, Psychology, Philosophy, and Dialogues with Carl R. Rogers and Harold Lyon, which outlines the findings of four formative pedagogical studies conducted over 20 years in 42 US states and six countries. The results suggest that teachers who demonstrate the features of empathy, genuineness, and positive regard in their interpersonal interactions with students have more positive effects in terms of student outcomes including attendance, achievement scores, interpersonal functioning, and rates of violence (Rogers & Lyon, 2014).

George Kelly

Nicole D. Ferris

Rutgers University– Camden

George Alexander Kelly was born on April 28, 1905 in Perth, Kansas. His childhood education was sporadic, and he was mainly homeschooled until he moved in with his uncle in Wichita, Kansas to attend high school. When George was 16, he transferred to Friends University academy where he took a combination of academy and college courses. After three years at Friends University, George Kelly transferred to Park College in Parkville, Missouri. He graduated in 1926 with a bachelor's degree in physics and mathematics. He went on to earn his master's degree in educational sociology, with labor relations and sociology minors from the University of Kansas in 1927. In the late winter of 1927–1928, he was offered a teaching position as a professor of Psychology and of Speech at Sheldon Junior College in Sheldon, Iowa. After a year and half at Sheldon Junior College, Kelly went to Edinburgh, Scotland to study education on an exchange fellowship. In 1930, he received his BEd from the University of Edinburgh. In 1931, he received his PhD in Psychology from the University of Iowa.

Later that year, George began teaching Psychology at Fort Hays State College. At this time, he was confronted by the distress people endured as a result of the Great Depression, and shifted his focus to, what he saw as the most needed of psychological services, clinical psychology. He opened the school's first Psychology Clinic, of which he was named director. The clinic offered free diagnostic, therapeutic, and assessment services to anyone in need. About two years later, Kelly, and a group of his students, started bringing clinical services to the teachers, parents, and children at schools across western Kansas. His experiences in the clinics had a significant impact on his work and between the years 1935–1940 Kelly published a collection of papers and abstracts concerned with the issues he saw in the clinical setting. Topics such as the everyday issues of clinical diagnosis, the use of diagnostic testing, clinical psychology in schools, and the developmental concerns of students, parents, and teachers were among those covered in these works (Krapp, 2005). These writings shed light on the influences the clinic at Fort Hays and the traveling clinics had on his thinking. Although Kelly later became known for his contributions to personality psychology, it was in clinical psychology that Kelly's unique contributions began. His 12 years at

Fort Hays resulted in more than 20 clinics a year at a collection of permanent branches that were established throughout Kansas (Chiari, 2017). In the first 20 years of the psychology graduate program, about 20 master's degrees were awarded, 15 of which were supervised by Kelly, and to this day Fort Hays State University still offers support services for students, faculty, and staff at their clinical center named after George Kelly (Chiari, 2017).

In 1943, George Kelly was commissioned to the United States Navy where his research ranged from instrument panel design to other issues of applied clinical psychology, like selection methods for naval cadets. In 1946, he was selected to be Professor and Director of the Clinical Psychology program at Ohio State University, where he remained for 19 years. In 1955, he published a two-volume series, *The Psychology of Personal Constructs,* outlining his theory of personality and its application in the clinical setting. Upon its publication, Kelly's work was recognized as a major development in the study of psychotherapy and personality psychology. He received invitations to lecture all over the world and held visiting appointments at many universities such as Harvard (1960) and Princeton (1962) (Chiari, 2017). In 1965, Abraham Maslow invited Kelly to serve as the Riklis Chair of Behavioral Science at Brandeis University in Waltham, Massachusetts. He wrote several manuscripts while he was at Brandeis, one of which "A Brief Introduction to personal construct theory" was published three times. Kelly was a charter member of the American Board of Examiners in Professional Psychology (ABEPP), as well as serving as its first vice-president, and subsequently its president. He was elected president of the Consulting Division of the American Psychological Association (APA) in 1954, and of the APA Clinical Division in 1956–1957. On March 6, 1967 George Kelly passed away from complications after a gall bladder surgery.

Kelly's work and contributions to the field are considered by some to be one of the greatest contributions of the decade to the theory of personality psychology (Fransella & Neimeyer, 2005). He proposed his personal construct theory (see Personal Construct Theory of George A. Kelly) at a time when psychoanalysis and behaviorism were the dominant perspectives in the field. When humans were seen as the products of their reinforcements and punishments (behaviorism) or their childhood experiences and unconscious desires (psychoanalysis), Kelly saw people as taking an active role in how they observe and interpret their surroundings. A fundamental belief of Kelly's that impacted his theory was that people created themselves and could re-create themselves if they had the courage and imagination to do so. Kelly's theory is a person-centered theory of personality. A person-centered theory, stems from Carl Rogers' person-centered therapy, believes individuals have unique perceptions of the world, and they use those unique perspectives to help them make sense of their dilemmas (Holosko, Skinner, & Robinson, 2008). George Kelly's theory of personal constructs agrees with this and suggests that people develop their own personal ideas about how the world works and then use those personal ideas to make sense of their observations and experiences. This differs from other person-centered theories because it does not impose its own set of theoretical concepts. Instead, personal construct psychology respects people's own interpretations of themselves and of their lives. This contrasts with other popular theories of personality that put the sense making of a client's experience on the psychologist. Kelly rejected this popular belief that the therapist's interpretation of a client's experience was the key to change because he realized that the key to change lay in what the clients did with the therapist's interpretations. The only condition for useful

interpretations by a therapist was that it be relevant to the client's problem and hold novel implications for a potential solution (Fransella & Neimeyer, 2005).

Personal construct theory functions under the assumption that we see the world as being real and the psychological processes we have are based on our personal versions of that reality. The personal versions of reality are people's personal constructs. Constructs are not permanent, but rather are subject to revision and change as our life experiences change the perception we have of the world around us. Additionally, all of the events that occur in the world are open to multiple interpretations, which Kelly referred to as constructive alternativism. Kelly believed that when making sense of a situation or event, an individual has the ability to choose the construct they wish to use, which can happen in real time as the event occurs, but can also happen via reflection allowing the person to look back and change their view of the event. George Kelly believed that human beings are a lot like scientists, seeking to understand the world around them through making predictions and then using their experiences to validate or invalidate those predictions. He argued that people interpret a situation in a particular way and then act deliberately with those interpretations in mind. Modifications of an action are a result of whatever outcome the individual expected through their experience. Therefore, the individual has used his or her interpretation as a scientific hypothesis, with the subsequent actions resembling scientific research or experiments (Krapp, 2005).

George Kelly believed that as individuals live their lives they perform experiments that test their personal constructs. If the experiment works, the person receives validation for that construct, ultimately strengthening their beliefs. If it does not work, their construct is invalidated which pushes them to change their beliefs to better fit the world they live in. Kelly (1963) also made a point to differentiate validation from reinforcement by explaining that a person who predicted they would win $10 from a wager, but won $15 would still be distressed because their prediction was not verified. This system of prediction making and verification is important because according to personal construct theory, people experience the world around them through their personal constructs. As individuals go through their day-to-day lives, their experiences are constantly validating, or invalidating those constructs, which are ultimately shaping their behaviors, feelings, and thoughts.

A person's psychological processes are exhibited by the ways in which that person anticipates events, suggesting that people move, or have a motivation, toward a better understanding of what will happen. Kelly believed that the constructs people use are chosen because they reflect things that occur frequently in their experience. He also believed that people tend to hierarchically organize their constructs so that more rudimentary constructs lie at the base of the hierarchy and more intricate ones lie on higher levels. Constructs that have been validated are stored away for future use. Ones that have been invalidated, must be reconsidered to better determine when and how to use it, whether it needs reconstructing or refining, and in some cases whether it should be abandoned all together. Constructs are dichotomous, or exist of two opposing sides. The side of the construct that is applied to a given situation is known as the emergent pole and is on the likeness end, and the side not being applied is the implicit pole and is on the contrast end.

To effectively identify and understand the ways in which an individual construes their experiential reality, Kelly devised the repertory grid. This technique is made up of three parts: elements, constructs, and links (Tan, 2002). A topic is selected and is usually about

some part of the individual's experience, (i.e. personal relationships). Examples or instances of that topic are listed, which are referred to as the set of elements (i.e. father, boss, wife, friend). Once the elements are listed, the client considers the elements three at a time and is asked to distinguish how two are alike but are contrasted to the third (Tan, 2002). For example, a client may group their father and wife together because they are calm, but distinguish their boss as a contrast because they are tense. Thus, the construct of calm/tense has been identified. Then the client rates the elements on the construct, usually with a five- or seven-point scale. This continues as the client works through further triads, thus extracting additional constructs until no further constructs can be obtained. The elements are then rated across constructs, providing insight into the links between different elements across the elicited constructs (Tan, 2002). The repertory grid can be analyzed to provide accurate, operationally defined articulations of an individual's constructs or personal values.

Agreeableness

Renée M. Tobin[1] and William G. Graziano[2]

[1] *Temple University*
[2] *Purdue University*

Personality is the collection of stable characteristics that make up an individual. Social scientists, especially psychologists, focus on examining core individual differences that comprise personality. In the absence of complete consensus about the structure of personality, the Five Factor Model of personality is widely regarded as the most comprehensive representation of the major domains of human personality (McCrae & John, 1992). These five superordinate domains include agreeableness, a latent variable expressed in behaviors indicating generosity, trustfulness, and kindness.

Graziano and Eisenberg (1997) describe Agreeableness as the domain of personality concerned with individual differences in the motivation to maintain positive interpersonal relationships with others. Graziano and Tobin (2013) formally define Agreeableness as a "set of interrelated dispositions and characteristics, manifested as differences in being likable, pleasant, and harmonious in relation with others" (p. 347). Agreeableness is seen as a graded continuum, but it is often useful to discuss attributions of persons at the extreme ends (e.g. persons low in agreeableness vs. persons high in agreeableness). Theoretically, Agreeableness maps onto the major motivational system of communion, or the desire for unity, intimacy, and solidarity with others (Wiggins, 1991). Individuals high in Agreeableness are better liked by peers and have more friends relative to their peers (Graziano & Tobin, 2009; Jensen-Campbell et al., 2002), likely because persons high in Agreeableness tend to find similarities with others, have fewer prejudices, and experience more empathy toward others (Graziano, Bruce, Sheese, & Tobin, 2007; Graziano, Hair, & Finch, 1997; Graziano, Habashi, Sheese, & Tobin, 2007; Habashi, Graziano, & Hoover, 2016).

In modern scientific research, systematic examination of agreeableness began as a result of reliable empirical regularities arising in descriptions of others, and later in self-descriptions (Digman & Takemoto-Chock, 1981). Other labels used to describe the dimension are *tender-mindedness*, *friendly compliance versus hostile noncompliance*, *likeability*, and even *love versus hate*. Research shows that persons who are described as "kind" are also described

as "considerate" and "warm," implicating a superordinate dimension that is relatively stable over time and related to a wide range of thoughts, feelings, and social behaviors. Agreeableness appears in free descriptions and in ratings in every cultural group studied so far (Kohnstamm, Halverson, Mervielde, & Havill, 1998).

Measuring Agreeableness

Agreeableness is typically assessed through self-report measures. Several psychometrically sound measures are available in the US and over 40 other languages (see the Goldberg et al. (2006) International Personality Item Pool (IPIP) at ipip.ori.org/newItemTranslations.htm). Measures include one-word adjective markers (Goldberg, 1992) and questionnaire formats such as the Big Five Inventory (BFI; John & Srivastava, 1999) or one of the versions of the NEO (Costa & McCrae, 1988). Beyond self-report measures, differences in Agreeableness can be measured through observation by knowledgeable informants such as spouses (Costa & McCrae, 1988), employers (Hogan, Hogan, & Roberts, 1996), and teachers (e.g. Digman & Takemoto-Chock, 1981). Overall, the measures show some variation, but more remarkable is their convergence. Samples of young children and non-US samples tend to yield lower internal consistency scores for Agreeableness than do American and European samples (e.g. Soto, John, Gosling, & Potter, 2008).

Given that it is generally considered better to be kind, warm, and considerate, self-reported agreeableness could be mistaken for "social desirability" and self-favoring bias. After all, self-reports of kindness and generosity may be reflecting a different latent variable; it may be masking darker motives to look good in the eyes of others. Systematic investigation, however, does not support the hypothesis that agreeableness is primarily an expression of self-favoring biases (Graziano & Tobin, 2002).

Agreeableness Research and Theory

Like most psychological constructs, Agreeableness can be understood in terms of thoughts, feelings, and behaviors that are related to it. Overall, agreeableness seems to be positively related to adaptive social behaviors (e.g. conflict resolution, emotional responsiveness, helping behavior) and negatively related to maladaptive social behaviors (i.e. prejudice, stigmatization). These relations have been found both in correlational studies as well as in stronger experimental ones.

In terms of outcomes, Agreeableness has been linked to a range of seemingly diverse criteria. One outcome that is consistently related to Agreeableness is conflict resolution. Graziano, Jensen-Campbell, and Hair (1996) found that most of their participants endorsed negotiation and disengagement tactics in resolving conflict, but the difference between persons low and high in agreeableness was greatest when destructive tactics (e.g. power assertion tactics such as physical force) were considered. In particular, persons low in agreeableness reported that destructive tactics were generally more acceptable than did their peers. These findings have been replicated with various methodologies using independent samples ranging in age from childhood through adulthood (e.g. Field, Tobin, &

Reese-Weber, 2014; Gadke, Tobin, & Schneider, 2016; Graziano et al., 1996; Jensen-Campbell & Graziano, 2001). Further, individuals high in agreeableness tended to perceive less conflict in their social interactions, report more liking of interaction partners, elicit less conflict from their partners, and are perceived by others as displaying less tension in their interactions relative to their peers. Thus, across age ranges and methodologies, agreeableness is linked to constructive resolution of conflict, presumably because of its underlying motives to get along with others. Similarly, Agreeableness is inversely linked to prejudice (Graziano, Bruce et al., 2007). Individuals high in Agreeableness are less likely to discriminate against out-group persons relative to their peers.

Processes of emotion are also tied to Agreeableness. Tobin, Graziano, Vanman, and Tassinary (2000) found that individuals high in Agreeableness experience stronger emotions and make greater efforts to regulate their emotions when asked to communicate about their experiences following exposure to emotionally evocative images than do their peers. One emotion in particular, empathy, is related to Agreeableness. Among the five dimensions of personality, Agreeableness is the only one that is significantly correlated with both of the major aspects of prosocial emotions, namely empathic concern and personal distress (Graziano, Habashi et al., 2007). Individuals high in agreeableness report greater ease taking another person's perspective and feeling the distress of others, but not necessarily in experiencing self-focused negative affect when observing victims who are suffering. Beyond their reported emotional experiences, Agreeableness is also tied to behaviors associated with empathic responding: Individuals high in Agreeableness are more likely to offer assistance to a victim in need than are their peers.

Future Directions in Research, Theory, and Methodology

Drawing on Dijker and Koomen's (2007) work, we have recently used the Opponent Process Model to explain the processes underlying Agreeableness (Graziano & Habashi, 2010; Graziano & Tobin, 2009, 2013). In this model, two systems based in human evolutionary history are at work simultaneously: Fight/Flight and Care. The older component, the Fight/Flight system, is activated first and without conscious deliberation, priming a system to flee from danger, or to fight if forced to do so. The second system, Care, is newer in evolutionary time and is associated with kin selection. It has the capacity to suppress the Fight/Flight system and has been theoretically linked to the personality dimension of Agreeableness. That is, Agreeableness has been conceptualized both as fairly direct expressions of Care and as a product of Care-based suppression of Fight/Flight. Concretely, persons high in agreeableness may feel empathic concern directly for victims of misfortune (Graziano, Habashi et al., 2007), but they may also have skills with suppressing (perhaps using effortful control) negative reactions to traditional targets of prejudice generated by their Fight/Flight system (Graziano, Bruce et al., 2007). Graziano and colleagues have adapted the Solomon and Corbit (1974) Opponent Process Model to explain the dynamic processes underlying the connections between Agreeableness and diverse outcomes. Additional research is necessary to examine the extent to which this conceptualization of Agreeableness is supported.

Individual Psychology of Alfred Adler

Angela M. Sabates

Bethel University

Firsthand experience with the ravages of World Wars I and II presented many challenges to Alfred Adler and his contemporaries. Aside from obvious economic, political, and social challenges, individuals were forced to reckon with their views of humanity. Are we, as the brutalities of the war suggested, inherently selfish and cruel, or is there some goodness in us? This central question arguably serves as a key distinguisher between Adler's and Freud's views. In his *Civilization and Its Discontents*, Freud (1930/1961) had famously insisted that underneath it all, humans are "savage beasts." Freud further asserted that when the constraints of a civilized society are removed, "man is a wolf to man." This aggressive instinct, according to Freud, coupled with the (mostly) unconscious sexual drive of humans, result in destructive and deadly consequences if left unchecked.

Adler instead claimed that humans are capable of acting in socially just ways, and not just when we are repressing our savage instincts. Moreover, Adler did not believe that repression resulted from civilized society's attempts to restrain instinctual drives. Adler instead claimed that all humans have the potential for other-centered concern and that mentally healthy individuals learn how to adapt their drives in socially accepted ways. Adler's belief in positive human potential has led some researchers (e.g. Watts, 2015) to suggest that Adler could be considered the original positive psychologist. These distinctions in underlying assumptions of the human condition are one way we can understand how Adler's theory continued to develop after his resignation from Freud's Psychoanalytic Society in 1911.

In contrast to Freud's assumption that humans are motivated primarily by sexual and aggressive impulses (the pleasure principle), Adler proposed that our basic desire and goal is to belong and feel significant (Fisher, 2001). This assertion, along with many others (e.g. people are motivated by social forces and often have feelings of inferiority) have become so mainstream that Adler's origination of those ideas has often been forgotten (Mosak & Maniacci, 1999). Adler was sometimes criticized for the simplicity and commonsense nature of his insights. Yet, close consideration of Adler's ideas reveal the depth of his

observations. Indeed, as noted by Mosak and Maniacci (1999), the simplicity of Adler's ideas belie their actual complexity.

Tenets of Individual Psychology

Adler's approach is alternately called "Adlerian Psychology" or "Individual Psychology." The word "individual" in Adler's theory is sometimes erroneously understood as deriving from a focus on individuals (Watts, 2015). In fact, the term is derived from the Latin, "individuum," meaning indivisible. Adler stressed the unity of the person. In contrast to Freud's reductionist idea that humans are comprised of different conflicting impulses, Adler maintained that humans should be perceived in a holistic manner, emphasizing the interrelatedness of persons' cognitive, affective, and behavioral dimensions.

Life Style/Style of Life

Adler's view of personality was centered on what he called style of life. This consists of a personally constructed metanarrative that a person develops throughout life from their unique experiences, motivations, personal beliefs, and goals (Watts, 2015). This metanarrative helps an individual face life's challenges and tasks. It is refined throughout life and is influenced by one's socio-cultural context, including both the larger culture and the culture of one's family. For example, within the family culture, one's position in the family, i.e. one's "psychological birth order," influences one's construction of their life style.

Just as Freud had stressed the importance of early family relationships in the development of personality, Adler maintained that early family experiences help shape our life style. For example, Adler noted that one's inclination to trust or distrust others is influenced by early experiences with family members who prove to be either generally trustworthy or not. And though Adler acknowledged these early influences, he did not believe that one is determined by them to the degree that Freud claimed. Instead, Adler believed that the impact of early family experiences can also be altered with time and other experiences because we are active agents in our growth. Thus we are proactive, as opposed to reactive, with regard to the development of our style of life (Carlson et al., 2006). This proactivity is what Adler referred to as the "creative self."

According to Adler, then, humans' personality growth is a very subjective and also hopeful process. Rather than simply reacting to the impact of life's situations; we create realities by how we perceive what has happened. This phenomenological perspective of the world means that perceptions can change, and humans are not victims chained to their past negative experiences. Instead, our experiences can be re-created and perceived in a new way (Foundational Adlerian Principles, n.d.).

In contrast to Freud's determinist perspective, Adler asserted that humans are proactive agents in their lives, capable of making choices and assuming responsibility for those choices. Adler acknowledged the influences of environment and genetics, but maintained that the metanarrative that guides one's life can be altered significantly by choice.

Gemeinschaftsgefuhl (Community Engagement/Social Interest)

Adler's focus on the power of individuals to create their personal life styles is coupled with an emphasis on the relational nature of humans, which is central to Adler's theory. Indeed, Adler noted that persons cannot be adequately understood outside of their social context (Watts, 2015). Adler's concept of gemeinschaftsgefuhl has two specific aspects. *Community feeling* refers to a sense of belonging, empathy, caring, compassion, etc. Those affective responses lead to *social interest*, the other important aspect of gemeinschaftsgefuhl. Social interest refers to behaviors and thoughts, such as care for the poor and marginalized, that contribute to the common good.

Social interest results in a sense of connection and embeddedness for the individual (Barlow, Tobin, & Schmidt, 2009). It is learned and practiced from childhood on. Adler claimed that sufficient social interest is essential to positive mental health and the ability to fulfill life's three greatest tasks: occupation, social relationships, and love.

According to Adler, positive individual functioning is inextricably interwoven with social relatedness. Humans are driven primarily by relationships, and the meaning of one's life is related to the contributions one makes to the well-being of others (Stone, 2011). This assertion directly contrasts Freud's claim that humans are not disposed to do good to others and his limited interest in patients' social relationships other than ones that contributed to the patient's trauma.

Striving for Perfection/Superiority

Adler proposed that in addition to being socially motivated, humans wish to feel competent, but they often feel a deep sense of inferiority. Adler used the term *inferiority complex* to refer to feelings of incompetence. Sometimes this sense of inferiority is prompted by the limitations imposed by a physical ailment (as was the case for Adler), negative messages one has received from family members, a sense of one's own inferior performance in relation to someone else's, etc. Adler claimed that it is not these messages or situations themselves, but rather our interpretation of them that lead to the perceived reality that we are inferior. We long to overcome this feeling of inferiority and become a thriving member of the community. Unlike Freud, who claimed that humans are driven by the pleasure principle, Adler maintained that we are driven by the "will to power," which refers to the person's creative drive to better themselves (Ansbacher & Ansbacher, 1964).

Adler proposed that humans attempt to satisfy their natural human tendency for self-mastery and competence by either striving for perfection or striving for superiority (Watts, 2015). He claimed that mentally healthy individuals deal with feelings of inferiority by *striving for perfection*, which involves striving toward a greater sense of competence for oneself and others. Individuals' social interest is related to many factors (e.g. hope, optimism, moral reasoning, etc.) that are indicators of good mental health (Barlow, Tobin, & Schmidt, 2009). *Striving for superiority*, in contrast, entails a more narcissistic, selfish attempt to overcome feelings of inferiority by striving to be superior to others with little to no consideration for their good. Adler proposed that this approach is characteristic of those who are maladjusted and leads to poorer mental health and to destructive social relationships.

Unlike other contemporary theorists, then, Adler emphasized the role of community feeling and social interest in humans' striving to overcome feelings of inferiority. As noted earlier, because this striving occurs in a relational context it could be either socially useful or destructive.

Therapeutic Applications of Individual Psychology

Alderian therapy is optimistic, centering on human strength and potential. This therapeutic approach views people as creative and capable of progress and focuses on the importance of social interest in fostering both positive individual mental health and behavior that leads toward the common good. The main objective of therapy is to help the client replace their destructive, exaggerated self-protective stance with positive social contribution (Alfred Adler: Theory and Application, n.d.). Clients are encouraged to see how they may be contributors to the greater social context.

Adlerians' growth model of personality perceives clients as discouraged rather than sick. Because discouragement is believed to be a main contributor to emotional distress, Adlerian therapy is about encouraging rather than curing the client (Watts, 2015). This encouragement mainly takes the form of active listening, positive regard, noting clients' strengths, aiding clients' attempts to alter negative thinking patterns, etc. This approach assumes that encouragement helps clients believe what they thought was impossible (Alfred Adler: Theory and Application, n.d.). Encouragement leads to increased confidence and gratification in the client, thereby increasing cooperation with the therapist.

Adlerian therapy acknowledges that the unconscious is important, but assumes that conscious processes are more powerful (Ansbacher & Ansbacher, 1964). In fact, rather than construing the unconscious as a noun, like Freud did, Adler referred to the unconscious as an adjective, denoting something "not yet understood" or something we have not yet developed in clear concepts. For example, a client may not be aware of the motives for their destructive social behavior. In this case, Adlerian therapy would help the person bring these unconscious motives to light and then focus on conscious evaluation and challenge of the faulty premises that motivate negative social interactions.

Adlerian therapy is used with a broad range of psychological disorders. It follows both short-term and long-term formats, with individuals as well as couples and families. Its strategies may be broadly construed as psychodynamic. Yet the strategies of cognitive-behavioral, systems, and positive psychology are often unwittingly built upon Adlerian foundations. Mosak and Maniacci (1999) noted that there has been so much integration of Adler's ideas into contemporary psychology that the proper question is not whether one is an Adlerian, but how much of an Adlerian one is (p. 8).

Animal Personalities

Andrew Sih, Amelia Munson, and Lea Pollack

University of California, Davis

Introduction

Many people would likely be comfortable with the notion that some mammals (e.g. monkeys, dogs, cats, perhaps lab rodents) have personalities, but might be surprised to learn that animal behaviorists have quantified personalities in all major vertebrate groups, and in numerous arthropods (insects, spiders, crabs, lobster), mollusks (octopus, squid, snails), and other invertebrates including organisms like sea anemones that lack a brain. To clarify, for animal behaviorists, the concept of "personality" differs from the APA's definition that "personality refers to individual differences in characteristic patterns of thinking, feeling and behaving". Instead, for animals the concept focuses on statistically repeatable patterns of behavior per se, usually focusing on ecologically important behavioral axes: boldness, aggressiveness, activity, sociability, and exploratory tendency (Reale et al., 2007). That is, we find that within any given species, some individuals tend to be consistently bolder, or more aggressive, or more sociable etc. than others.

Quantifying Animal Personalities

Animal personalities are typically quantified by observing each animal's behavior (at least twice) under standardized assay conditions. For example, in the open field assay, each individual starts in a safe refuge. Individuals that leave more quickly are termed "bolder," and those that cover more area after leaving are more "active" or if it's a novel space, more "exploratory." Boldness is often further assessed by exposing individuals to a threat (e.g. a simulated predator attack).

When different assays involve different ecological contexts (e.g. fighting, mating, and avoiding predators), we test for "behavioral syndromes," behavioral correlations across ecological contexts (Sih et al., 2004). For example, individual differences in aggressiveness in fights have

been found to be positively correlated to male aggressiveness toward females (sexual coercion), negatively correlated to parental care effort (feeding of offspring), and positively correlated to boldness in the presence of danger.

Many behavioral type (BT) axes in animals relate to variation in a "risk-reward trade-off." Individuals that are more bold, aggressive, and active take more risks with potentially larger associated rewards. Shy, unaggressive and inactive individuals take fewer risks with smaller associated rewards. Animal personality then mediates a growth-mortality, life-history trade-off, with bolder individuals growing quickly and reproducing at a younger age, versus cautious ones growing slowly but surviving longer to reproduce at a later age (Reale et al., 2010). The fitness of each BT typically depends on the environment; e.g. bold, aggressive individuals often do well in resource limited, competitive environments with low predation risk while cautious, unaggressive ones are favored in high predation environments.

Genetic Mechanisms

Heritabilities of BTs have been measured for numerous animals. Although heritability of behavior can be quite low in animals, the heritability of personality is typically much higher. A recent meta-analysis found that approximately 52% of animal personality variation is due to additive genetic variation (Dochtermann et al., 2015). Evidence of genetic correlations between behaviors has also been observed in animal models.

Various candidate genes that are studied in humans (and rhesus monkeys and other model systems) also appear to influence variation in animal personality. In several vertebrate taxa, the dopamine receptor (DRD4) appears to play a role in modulating exploratory and risk seeking behavior, and the serotonin transporter (SERT) appears to play a role in modulating aggression, anxiety, harm avoidance, dominance, and sexual behavior. Other vertebrate candidate genes associated with variation in BT include genes associated with the neuropeptides of the arginine vasotocin (AVT) family. For invertebrates, candidate genes linked to different BTs have been suggested for aggression in fruit flies, honeybees and crayfish, among others. Most of the work on these candidate genes has been on model systems often using laboratory selection lines. However, growing evidence suggests the importance of these neurotransmitters in regulating personality in various non-model vertebrates. As with humans, the percentage of variation explained by candidate genes is typically low, which is not surprising since in most cases, many genes are thought to influence behavior.

Neuroendocrine and Physiological Mechanisms

Different BTs are associated with distinct patterns of autonomic nervous and endocrine activity (Koolhaas et al., 2010). In mice and rats, aggressive and proactive males are characterized by high reactivity of the sympathetic nervous system and high baseline activity and stress reactivity of the HPA-axis. Outside of mammalian models, post-stress plasma cortisol levels have been correlated with coping style behavior in several species of fish and birds.

pace of life
slow ←——————→ fast

life history
long life ←——————→ short life
delayed reproduction ←——————→ precocious reproduction
low growth rate ←——————→ high growth rate

behavior
low activity ←——————→ high activity
low level of aggressiveness ←——————→ high level of aggressiveness
shy ←——————→ bold
neophobic ←——————→ neophilic
thorough exploration ←——————→ superficial exploration
philopatric ←——————→ high dispersal
social ←——————→ asocial
high level of parental care ←——————→ low level of parental care

physiology
high HPA axis reactivity ←——————→ low HPA axis reactivity
low sympathetic system reactivity ←——————→ high sympathetic system reactivity
high parasympathetic system reactivity ←——————→ low parasympathetic system reactivity
low metabolism ←——————→ high metabolism
low sensitivity to oxidative stress ←——————→ high sensitivity to oxidative stress
high immune response ←——————→ low immune response

cognition
slow sampling ←——————→ fast sampling
high accuracy ←——————→ low accuracy
risk averse ←——————→ risk prone

Figure 1 A summary of traits, including behavioral types, associated with slow versus fast lifestyles. Adapted from Reale et al. (2010) and Sih and Del Giudice (2012).

Differential expression of neurotransmitters and neuropeptides can also have an important role in BT differentiation. For example, high levels of aggression are associated with low levels of serotonin in lab rodents and stickleback fish. Vasopressin and oxytocin signaling also play a role in governing proactive or reactive coping styles in mammals.

Recent work suggests that metabolic rates are often related to consistent individual differences in behavior (Biro & Stamps, 2008; Careau et al., 2008). This hypothesis is connected to a Pace-of-Life framework proposed by Reale et al. (2010), which suggests that proactive animals have higher metabolic rates than reactive individuals. As noted earlier, activity, exploration, boldness, and aggressiveness are considered to be energetically costly, "high risk, high demand, high reward" activities (see Figure 1).

Effects of Early Experience on Personality

Early social stress (e.g. separation from mothers) can result in personalities that are poorly adapted to future social life. This has been particularly well documented in mammals but has also been examined in other vertebrates (e.g. fish) and invertebrates (e.g. crickets).

Experimental exposure of juveniles (or even embryos) to danger (e.g. predation risk) has also been shown to effect later personality (e.g. fearfulness); much of this work has been on fish.

A recent subject of interest has been transgenerational plasticity; here, the effect of stresses experienced by parents on the development of their offspring's personalities. For example, female stickleback fish exposed to predator cues for just a few minutes produce eggs with higher levels of cortisol, and thus have offspring with fearful personalities. Perhaps even more interestingly, male sticklebacks exposed briefly to predator cues apparently alter their parental care in ways that also shape their offspring's future behavior.

On the conceptual front, an exciting focus has been on whether the effect of early experience on the development of personality is adaptive (Sih, 2011). An earlier view was that early stressors (e.g. social stress, or exposure to danger) produce poorly adjusted BTs. An alternative view posits that early stress prepares organisms for coping with stress later in life. For example, the "adaptive tuning" model suggests that there is no optimal level of stress, instead as long as the early environment is a good predictor of the future environment, the level of stress experienced during development should prepare the individual to respond appropriately later in life.

Cognition and Learning

Many aspects of cognition, including perception, learning, memory, and decision making, have been well studied in non-human animals. Historically though, the emphasis has been on species-level abilities and interspecific differences in cognition. The recent interest in animal personality, however, has led to new focus on consistent individual differences in animal cognitive abilities. One hypothesis is that the relationship between an animal's personality and its cognitive style depends on where it falls on a speed-accuracy trade-off (Sih and Del Giudice, 2012). This trade-off suggests that an individual can either make decisions quickly or accurately, but not both. Individuals that are bold, aggressive, and asocial may be more likely to make decisions quickly (with less time taken to collect and carefully process information) with less accuracy than shy, less aggressive, more social individuals. BTs that emphasize speed over accuracy might also be more risk prone (as opposed to risk averse) and impulsive.

Social Behavioral Ecology and Personality

Many personality traits are either only expressed in the presence of other individuals (e.g. aggressiveness) or are affected by the social environment. In turn, personality affects social dynamics for mating, contests, cooperation, and social foraging. Personality thus is interwoven with social behavioral ecology.

Indeed, social interactions might be a key factor that generates and maintains consistent personalities in animals. The concept of "social niche specialization" proposes that an animal exhibits a stable personality because others within a social group induce the individual to consistently fill a specific role with an associated BT (Bergmuller and Taborsky, 2010). The role might involve a social rank, a position in the social network, or a role in group foraging or antipredator behavior.

The mix of personalities in a social group, or the personality of key individuals can have major effects on group social dynamics. An exciting recent approach has involved the experimental creation of groups with different mixes of personalities (e.g. groups with different proportions of aggressive individuals) to quantify effects on mating dynamics, collective foraging, colony defense, intergroup competition, collective learning, and ultimately, group-level survival.

Ecological Implications

Animal personalities and behavioral syndromes can also have important implications for ecology (Weissing et al., 2012; Sih et al., 2012). BTs influence survival and reproductive success and thus population growth rates. The outcome of a predator-prey or competitive encounter can depend on the BTs (boldness, aggressiveness) of both species, and most interestingly, on the interaction between their BTs. Disease transmission can also be mediated by BTs through effects on host social networks. More active and social hosts tend to have larger social networks, and thus have higher potential to both pick up and spread socially transmitted diseases.

At a larger spatial scale, personality-dependent movement patterns can influence ecological invasions. For example, more aggressive and asocial individuals might have a higher tendency to disperse and colonize new habitats, and in many cases, bolder, more aggressive, or asocial individuals might thrive better in newly invaded sites. Indeed, conventional wisdom suggests that pioneers in the American West might have had these personality traits. In contrast, if cooperation is necessary, more social and less aggressive individuals might be necessary for successful colonization.

BTs also play a role in governing behavioral responses to human-induced rapid environmental change (HIREC). More exploratory or more flexible individuals tend to respond better to novel conditions. In particular, an active area of interest is in the influence of BTs on animal tendencies to urbanize. Bold or aggressive BTs are often more likely to tolerate humans and colonize human habitats, but boldness can obviously be detrimental if novel situations are dangerous.

Conscientiousness

Margaret L. Kern

The University of Melbourne

Introduction

Conscientiousness refers to a group of personality traits that represent a person's tendency toward being self-controlled, persistent, industrious, and orderly. It is one of the major factors of the Big Five model of personality, and predicts numerous desirable outcomes. Conscientiousness is an important part of the moral and social compass of society.

History and Assessment

Conscientiousness-type traits have appeared throughout history in philosophy, theology, education, and business (Ryans, 1939). Across the 1900s, it was conceptualized as a moral characteristic, reflecting a strong work ethic and being a socially responsible citizen, which aligned well with the values and work ethos of many Western countries. Measurement and conceptualizations of conscientiousness went hand in hand. Items related to conscientiousness were included in surveys across the twentieth century. Beginning in the 1920s, several researchers developed behavioral tasks that tested how long a participant would persist in a task. For instance, the Character Educator Inquiry introduced a series of eight tasks to study persistence, inhibition, and self-control in children, including story resistance, puzzle mastery, fatigue and boredom in mental work, solving a toy puzzle, and standing on one foot. Similar approaches later appeared through delay of gratification (e.g., Mischel's marshmallow task) and executive control designs (e.g., the Stroop test).

The twentieth century brought the dominance of factor analytic approaches to personality (Kentle, 1995). This involved compiling lists of adjectives, collecting self-ratings across diverse populations, and factor analyzing the responses. Based on survey questions, conscientiousness-type factors were identified that reflected moral qualities (e.g., maturity, good nature, kind by principle, tact) and persistence. Increasingly, a coherent five-factor structure emerged (extraversion/ surgency, agreeableness, conscientiousness,

emotional stability/ neuroticism, intellect/ openness), which became known as the Big Five (cf. John & Srivastava, 1999). While scholars disagree on the exact labels and the traits that fall within each domain, the model provides an organizing framework for considering associations between personality and other outcomes of interest, and dominates much of the research, theory, and practice related to conscientiousness.

Other approaches to assessing conscientiousness include behavioral observations, ratings of one's home or workspace, analysis of one's social media behavior and language, and correlated structures within the brain. Different methods are only moderately correlated; most likely different approaches capture different aspects of the person.

Structure

Conscientiousness lies on a continuum, with most people falling somewhere in the middle of two extremes. Conscientious individuals might be described as disciplined, dependable, diligent, organized, hardworking, careful, thorough, efficient, planful, and socially responsible. Individuals low in conscientiousness tend to be more impulsive, spontaneous, easy-going, irresponsible, disorganized, lazy, reckless, and indifferent.

From the Big Five perspective, personality is hierarchical in nature. At the highest level, conscientiousness groups together with agreeableness and emotional stability as a socio-emotional maturity factor. Facets cluster beneath the main factor, including discipline, order, and achievement-orientation. These facets include more concrete trait descriptors (e.g., self-control, organized, and diligent), which are manifested as specific behaviors (e.g., avoid a high-calorie dessert, keep workspace clean, pushing through an assignment until it is complete).

Benefits of Conscientiousness

Conscientiousness and its various facets has been linked to good physical and mental health, occupational success, stable marriages and families, less crime, and good citizenship behaviors (e.g., paying taxes, voting). It predicts longevity, resulting in an up to four-year advantage for those in the upper versus lower quartiles of conscientiousness (Kern & Friedman, 2008). However, at extreme levels, conscientiousness can become maladaptive, with the persistence, ambition, perfectionism, and achievement striving facets exhibiting strong correlations with the compulsivity, propriety, and workaholism domains of obsessive-compulsive personality disorder (Samuel & Widiger, 2011).

Pathways

Various factors correlate with both conscientiousness and subsequent life outcome. Some are mechanisms, some are moderators, and some are confounding variables. Base levels of conscientiousness are rooted in genetic and environmental factors (South & Krueger, 2014). Genetic propensities might manifest in different ways, depending upon the early

environment and subsequent life experiences. For example, secure attachments with the caregiver predict greater levels of self-regulation across childhood (Eisenberg, Duckworth, Spinrad, & Valiente, 2014), which in turn can set a trajectory toward more conscientious behaviors. Aspects of the social context, including socio-economic status, neighborhood safety, and aspects of the culture (including norms of what is socially acceptable) interact with a person's core tendencies to impact upon both the personality characteristics that a person manifests, as well as the acceptability of those behaviors in the society in which the individual resides.

Conscientious individuals are less likely to smoke, drink excessively, drive recklessly, and engage in high-risk activities. They are more likely to eat healthily, stay active, adhere to medical advice, and proactively take care of their health. They are more likely to be deliberate in how they spend their time and how they approach different situations. A conscientious individual might approach a holiday by carefully planning the itinerary, setting up reservations for travel and accommodations, pack extra clothes and food for the journey, and ensure that others know their plans, whereas less conscientious individuals might rely up on spontaneity. Some of the benefits that conscientiousness has might stem from the daily reduction of small risks, which add up over time to be protective.

Conscientiousness impacts how a person relates to and interacts with other people. Conscientious individuals are more likely to invest in work, family, religion, and volunteering (Lodi-Smith & Roberts, 2007), and experience better marital quality, lower rates of divorce, and social acceptance by others. Conscientious individuals are more adept at seeing and responding to the needs of others, and may be more attuned to the social context, identifying when a behavior is appropriate or inappropriate, and then showing the restraint to act accordingly. With a high drive for achievement, combined with an ordered approach toward getting things done, conscientious individuals are more likely to experience good work outcomes, including less unemployment, promotion, higher salaries, and being respected by colleagues.

Conscientious individuals also tend to take more active, approach-oriented approaches to stressors, seeing events as challenges instead of threats, and believing that they have the internal and external resources to cope (Carver & Connor-Smith, 2010). They are less likely to use substances to cope with stress, and make greater use of problem solving and cognitive restructuring techniques.

In sum, multiple pathways potentially connect conscientiousness to health and other outcomes. Personality impacts how a person behaves and thinks, as well as how a person experiences, makes sense of, and reacts to events throughout life (Caspi, Roberts, & Shiner, 2005), and these in turn impact the life outcomes that a person experiences.

The Dynamic Nature of Personality

Ratings on many of the personality questionnaires capture stable characteristics of the person. But personality is also dynamic in nature, varying across time and situations. An individual that is meticulous at work might live in a chaotic home. Traits manifest differently across contexts, and interact with experienced and constructed contexts, often in indirect, non-circular, and complex ways. Personality researchers have dealt with this complexity either by

aggregating across situations to remove the effect of context, or by bringing the person and situation together and searching for coherent explanations. Individuals seemingly have a signature style of stable, meaningful patterns in how their thoughts, feelings, and behaviors vary across situations (Mischel, 2004).

A challenge for the field is how to capture both the dynamic processes of the individual and stable individual differences, as well as better understand how conscientiousness impacts life outcomes. Fortunately, there is an increasing sophistication of data and methodologies available that can inform the inherent complexity of personality. For instance, numerous archival studies exist that have followed people over many years. These have mostly been studied separately, but with a move toward digitization and sharing of data, such studies can potentially be used to further explore what patterns matter most for different outcomes over time, as well as mechanisms and moderators involved.

As technology rapidly moves forward, there are growing possibilities for using electronically generated information, such as social media, electronic health records, mobile phone behaviors, among others, as unobtrusive measures of behavior, capturing how personality manifests in everyday life. By combining existing data, computational social science techniques, and rich personality theory, conscientiousness potentially can be studied in innovative ways that adequately capture its dynamic yet stable nature in a coherent manner.

The extent to which conscientiousness can be developed through intervention, and if so, what those interventions should entail, is mostly unknown. It is also unknown the extent to which changes in a person's level of conscientiousness will correspond with the benefits that have appeared in correlational studies. Interventions might target conscientious behaviors, the narratives that people construct of their lives, social structures that encourage conscientious behaviors, or specific facets of conscientiousness. The most effective approaches for intervention most likely depend in part on the context and individual.

Conclusion

Conscientiousness represents characteristics and behavioral patterns that allow an individual to persist through difficulty, resist temptation, set and meet goals, be thorough and reliable, maintain a sense of order, and exhibit a sense of responsibility to the self and the society in which one lives. It is valued across many cultures, and correlates with numerous positive, socially valued outcomes. Conscientiousness helps society run in an orderly fashion, and modern cultures will do well in continuing to support and develop conscientious citizens.

Cognitive-Affective Processing System (CAPS)

Andreana Dingess and Joshua Wilt

Case Western Reserve University

Core Ideas and Theoretical Importance

The CAPS is a model of human personality proposed by Walter Mischel and Yuichi Shoda. Personality is conceptualized as a stable system of cognitive and affective features that (1) processes situational information and (2) uses this information to generate behaviors. Thus, the model rests on the basic assumption that behavior in any given situation results from the interaction of cognitive-affective features of the person, features of the situation, and the interaction of the person and situation (Mischel & Shoda, 1995, 2008).

This model was conceived in an effort to resolve a historical controversy between personality psychology and social psychology, referred to sometimes as the personality paradox. The personality paradox contrasts a fundamental tenet of personality theory, the idea of personality as being consistent over time, with a foundational observation from social psychology, that behaviors are inconsistent across situations. The CAPS model is intended to integrate both sides of this apparent paradox by showing how there can be stability in a person's cognitive-affective system and yet variability the person's behavior in different situations. Consistency in personality is therefore not at the level of individual behaviors, and inconsistencies in behavior are therefore not solely attributed to the situation. Rather, a person's inconsistent behavior reflects one's stable patterns of cognitive and affective processes interacting with variability in the environment. That is, in the CAPS model, behavioral variability across situations is not error but is predictable when considering personal and situational variables.

Central Premises

The CAPS model is influenced heavily by the personal constructs theory proposed by George Kelly, one of Walter Mischel's graduate school mentors. Personal constructs are the mental representations that people use to interpret events, which are based on a

person's history of experiences and observations. Each person has a unique set of personal constructs that guide the person's thoughts and perceptions. This idea makes up the first main component of CAPS: An individual's construal of the world is an important determinant of how the person will respond to different situations. The second key component is a view that the CAPS processes thoughts, feelings, and goals simultaneously on multiple, separate tracks that occasionally interact with each other. The result of this processing is overt behavior.

Key Variables

Cognitive-Affective Units (CAUs)

There are five prominent CAUs, which are cognitions and affects or feelings that are available to the person. Four of the variables were identified in the original version of the theory called *cognitive social learning theory* (Mischel, 1973): encodings, expectancies and beliefs, goals and values, and competencies and self-regulatory plans. Encodings are internal or external categories for the self, people, events, and situations. Expectancies and beliefs can be held about the world (particularly the social world), outcomes for behavior, and self-efficacy. Goals and values are related to achieving desirable outcomes and affective states or avoiding aversive outcomes and affective states; they can be related to short-term plans or long-term life projects. Competencies and self-regulatory plans are potential strategies and scripts for organizing behaviors to affect internal or external outcomes. Mischel subsequently revised the model to include a fifth variable, affects, which are feelings and emotions (including physiological states).

The dynamic nature of the CAPS was an important theoretical advance over existing models of personality, which typically assumed a static, causal relationship between latent personality traits and manifested behavior. The CAUs in CAPS are not isolated, unchanging components, but interact and influence each other over time. CAUs can become activated, deactivated, influenced or not influenced by other CAUs. The organization of the relationships between CAUs form the core of the personality structure. The accessibility of CAUs, and the interactions among CAUs describe and explain how people experience stimuli and generate affect, behavior, and cognition. That is, CAUs are important determinants of observed individual differences in personality.

If-Then Contingencies

An important premise of CAPS is that situation perception activates CAUs. The distinctive pattern of CAUs that are activated by the cognitive processing system in response to stimuli generates actions and behaviors. In CAPS, these patterns of stimulus processing leading to behavior are called *if...then* contingencies: *if* a certain pattern of CAUs are activated...*then* specific behaviors will result. Each individual's pattern of *if...then* contingencies is unique and together constitute the person's behavioral signature.

To illustrate by example, *if* in a situation where people offer help, *then* person 1 may activate CAUs resulting in happiness and expressions of gratitude, but person 2 may activate CAUs resulting in unhappiness and ungrateful behavior. Consider these people

in the contrasting situation in which help is not offered. Person 1 is ungrateful to be left alone in this situation, whereas person 2 experiences gratitude, possibly due to valuing independence. Examples like these can be extended to other situations and extrapolated over time to result in a scenario in which person 1 and person 2 experience the same overall degree of gratitude over time. Thus, even if people are similar in their overall or average levels on a personality trait, each person's specific *if...then* pattern is different and predictable, reflecting the different CAUs activated across different situational features.

Mischel contends that *if...then* contingencies could replace personality traits (e.g. The Big Five, for example) as the fundamental units of personality. CAPS stipulates that *if...then* contingencies have more power than traits because the contingencies explain how people change and adapt across different situations rather than simply specifying an average level of expected behavior. Further, these contingencies have the potential to explain traits themselves by the social learning and cognitive mechanisms incorporated in CAPS (Funder, 1997). For example, traits such as introversion-extraversion may be understood in terms of relevant *if...then* contingencies in situations that prime for manifestations across the introversion-extraversion continuum, such as social, leadership, and appetitive (i.e. situations that involve active reward-seeking behavior) situations. It has also been proposed that *if...then* contingencies may apply to ideas from other historically prominent traditions in personality. For example, the psychodynamic concept of transference, the notion that people unconsciously transfer their feelings about one person to a second person who is reminiscent of the first, fits this paradigm: *If* a man meets a woman who reminds him of his mother, *then* he might think and act similarly to how he felt and behaved with his mother.

Applying CAPS to Important Psychological Phenomena

The dynamic nature of all of the components in the CAPS model working together is best illustrated by noting how personal constructs influence the ways in which different features of a situation activate CAUs in the encoding process. The pattern of activations across other CAUs over time and across multiple tracks ultimately produce aspects of experience such as plans, strategies, and observable behaviors. This general model can be applied to important psychological phenomena.

Rejection Sensitivity

Consider rejection sensitivity, a cognitive individual difference variable characterized by level of vigilance to cues signaling social rejection (the prototypical example is in the context of romantic relationships). The behaviors of people with high levels of rejection sensitivity are inconsistent: In one situation, a person in a romantic relationship may act kindly toward a partner whereas in another the person could be irritable and harsh. This pattern cannot be understood adequately within the context of trait theories that assume consistency in behavior. The pattern could also be confusing to the person's partner without invoking a CAPS-based framework (Ayduk, & Gyurak, 2008). Specifically, early attachment relationship experiences influence acceptance-rejection personal constructs as they

apply to later interpersonal relationships. Fears and expectancies of rejection are activated only *if* certain situational cues are present (thus explaining variability in different situations), which *then* lead to the rejection-sensitive behavioral pattern of overreaction.

Delay of Gratification

A classic application of the CAPS model is to the concept of delay of gratification, as shown by an experiment in which children were presented with a choice between two options that varied in reward quality: a pretzel or a marshmallow (cf. Mischel, 2014). Children were given the option of taking the less desired reward (pretzel) right away or taking the preferred reward (marshmallow) after a period of waiting. The goal of this study was to examine the strategies a child would use to endure a period of waiting. It was determined that how a child conceptualized the reward in terms of CAPS processes (i.e. construals and cognitive-affective expectancies), predicted delay of gratification. For example, it was easier for a child to avoid eating a pretzel if the pretzel was thought about as a stick, rather than thinking about the crunchy, salty taste. This experiment demonstrated the causal power of CAPS variables.

Psychological Disorders

Finally, CAPS is just beginning to be applied in the conceptualization and treatment of psychological disorders, particularly anxiety disorders (Borkovec, Ray, & Stöber, 1998; Shoda & Smith, 2004). Consistent with CAPS, *if* different environmental stimuli (or situational features in the CAPS parlance are present, *then* affect, behavior, and cognition related to anxiety is triggered). Future research could elucidate how these stimuli activate cognitive pathways that result in anxiety, as such knowledge may lead to ideas about how to reduce their triggering effects. Additionally, making changes to one's environment could avoid triggers, resulting in altering patterns of CAUs and hence more adaptive responses. Along these lines, such research could proceed to test how different types of environmental changes affect CAPS variables, such as encoding, expectancies, goals and values, competencies, self-regulatory plans and affects (each variable could be examined separately or simultaneously in correlational and experimental designs). Another area of possible research is looking at whether different *if...then* patterns characterize different individuals' anxious responses. According to CAPS, one type of response can have many underlying *if...then* patterns, so such tests may be instrumental to further validating CAPS as it applies to important psychological outcomes.

Cattell Trait Theory Lexical Analysis

Lucinda Woodward

Indiana University Southeast

History of the Lexical Approach to Personality

The lexical hypothesis was founded in sociolinguistic theory, in both England and Germany, in the early twentieth century (Fehringer, n.d.; Raad, 1994). According to this hypothesis, there are two assumptions about the cultural use of language: First, those personality characteristics that are important to a group of people will eventually become a part of that group's verbal utterances; and second, those personality characteristics deemed to be more important are more likely to be encoded linguistically as a single concept (Saucier & Goldberg, 1996). Early work in this field by Francis Galton and G. E. Partridge used Q-sort methods to examine a limited number of human descriptors thus narrowing the number of potential personality traits to a few hundred.

In 1936 Gordon Allport and Henry Odbert published their own factor analytic study of some 400,000 words used to describe personality or human behavior that were drawn from Webster's New International Dictionary. From this list, they identified 17,953 unique terms that could be applied to human personality traits. Their resulting study, which grouped these terms into four functional categories (Allport & Odbert, 1936; Winter & Barenbaum, 1999) became the foundation for Cattell's and others lexical researchers' work to follow. The first studies of personality dimensions were based on an analysis of 35 bipolar scales, passed on peer ratings of 373 male university students (Wiggins, 1996). Later studies included a sample of exclusively women and replicated roughly the same 11 dimensions found in the male sample.

The lexical approach marked a field-wide shift from theoretical to empirical study of personality. The overarching goal was to both describe and measure personality where a distinction between normal and abnormal is irrelevant (Cattell, 1946). This method generally starts with a large, broad pool of phenotypical characteristics and statistically groups ratings of trait adjectives into basic categories or units. According to Johnson (2017), Cattell's methods involved consolidating Allport and Odbert's initial list of 4,504 personality trait terms and reduced it to 160 clusters of terms that he and a fellow rater (a student of

literature) deemed to be either synonymous or opposites. From these clusters he selected 13 terms that embodied each grouping and added clusters representing intelligence, special abilities, and interests. Study participants then rated how characteristic or uncharacteristic each of the identified clusters was in describing a known acquaintance. Pearson correlations coefficients were evaluated to determine how strongly any two ratings were related (Cattell, 1943, 1945).

According to Johnson (2017), each of the correlations was calculated by hand and then printed on a 14-square foot table that was so large it had to be spread out on a gymnasium floor to view. Correlations larger than .83 were considered significant and thus, identical. Using this method, the initial 171 categories were reduced to 58 clusters. Further examination resulted in smaller and smaller numbers of categories until 35 groupings were achieved. These were the data Cattell utilized in his later factor analyses

The overarching goal of trait analysis is to identify the major dimensions of personality. Factor analysis is the statistical method used to achieve this objective. In factor analysis, groups of items that seem related, but do not co-vary with other items are identified, enabling the researcher to determine which personality variables share the same properties. It is useful in reducing a large array of traits into smaller sets of underlying factors. The factor loading is an index of the degree of variation in an item is accounted for by that dimension.

Cattell's research started by identifying words describing human behaviors and broke these down into multiple categorical types or unities (dynamic, environmental, logical/semantic/evaluative, constitutional, and developmental unities) and three general modalities (dynamic – changing, temperament – constant, and ability – learned) (Cattell, 1946).

Dynamic unities can be further deconstructed into two categories: dispositional (goal directed) and metanergs (the product of habits, sentiments, attitudes, and interests). Metanergs share a cultural understanding that makes them universally understood (i.e. "patriotic," "paternal," or "artistic"). Environmental unities describe the formation of a single pattern of behavior induced by environmental presses (or rewards and punishers), such as being a "good bicyclist." Logical/semantic/evaluative unities are purely logical/stylistic categorizations of behavior and have no relation to actual structure or function of the individual or the environment (i.e. someone termed "mechanical" or "charming"). Constitutional unities include behaviors that are unique to an organism and are not changing or related to environmental stimuli (i.e. "sensitive," "intelligent," and "excitable"). Developmental describes the simultaneous appearance of a group of characteristics or features that comprise a unity (i.e. "adolescent," "senile," "primitive," or any behavioral syndrome such as "depressive"). Finally, Other unities are anything not accounted for by another unit.

Cattell's Factor Analysis

Cattell's early access to sophisticated mathematical methods in his research position at the University of Illinois Champaign-Urbana was instrumental in his role as a multivariate research psychologist and statistician. Founder of the Society of Multivariate Experimental Psychology, he consulted internationally on research into human behavior using both multivariate statistics and factor analysis, enabling researchers to evaluate the whole person, rather than measuring single traits in isolation. Rejecting subjective theory

for more empirically sound statistical methods, he explored the basic dimensions of personality, motivation, and cognitive abilities in humans. One of the results of Cattell's application of factor analysis was his discovery of the theorized 16 separate primary trait factors within the normal personality sphere.

The 16 factors were later organized as described by Cattell (1946). The hierarchy of verbal constructs are arranged from widest reference to narrowest reference, with ordering dependent upon the relative strength of the general, group, or specific loadings of each factor. Overall, General Traits supersede Trait Configuration and Traits/symptoms supersede Elements. Cattell's initial analyses further resulted in two types of mathematical representations of traits: clusters (easily observable surface traits) and factors (underlying source traits). He observed that there are generally more inter-related clusters identified than true underlying factors. Significantly, clusters tend to be merely statements of statistically observed connections while factors are hypothesized interpretations of broader relationships between traits that are in part a function of theoretical orientation.

Cross-Cultural Validation

Eysenck and Eysenck (2013), purport that the vast majority of indices for trait factors (across both males and females) suggest that the personality dimensions in different countries are essentially similar and may even endorse the concept of identity. Consistent with the lexical hypothesis, valid measure of personality would be expected to vary cross-culturally, while high correlations would be anticipated where levels of cultural similarity overlap (Meisenberg, 2015). In a meta-analysis consisting of five cross-cultural studies of lexical factor theory, average correlations for each personality dimension across international samples indicated acceptable correspondence internationally. The factors Neuroticism, Extraversion, and Conscientiousness produce the highest correlations while Agreeableness and Openness are the least valid. Likewise, examination of TESOL results have confirmed the factors introversion/extraversion and risktaking (Shalabi & Nodoushan, 2009).

Development of Personality Assessment Using the Lexical Approach

The 16PF marks the first attempt to use statistical methods to map the primaries and secondaries of personality dimensions for the purpose of describing and diagnosing personality types (Cattell, 1989). The 16 dimensions associated with the 16PF include:

1) Affectothymia-Sizothymia: The warm-cool orientation
2) Discerning Relationships: Intelligence
3) Adaptation to the Environment
4) Control and Deference in Human Relations
5) Exuberant and Somber orientations
6) Content and Action of Moral Values

7) Boldness and Timidity in Human Temperament
8) Feeling vs. Thinking – Contrasting modes of evaluating experience
9) Alienation vs. Identification in Social Orientations
10) Intuiting and Sensing as Contrasting Perceptual Modes
11) Self-Presentations in Social Situations
12) Guilt Proneness and Untroubled Adequacy
13) Orientation Toward Change
14) Self-Sufficiency vs. Group Dependency
15) Investment in Maintaining a Socially Approved Self-Image
16) Tense and Relaxed Temperaments

Critiques of Cattel's Lexical Model

One of the primary issues brought up about the lexical approach addresses limitations of human language. First, not all human descriptors are personality relevant. Second, there are many terms that are used metaphorically that are not phenotypic descriptors of human behavior and that are systematically eliminated from analysis. Third, person descriptors can include nouns, verbs, and adjectives, but in languages with few adjectives, it is unclear what words should be analyzed (Saucier & Goldberg, 1996). Fourth, language accounts for a minority of human communication and does not sufficiently describe human experiences (Mehrabian, 1971). Lastly, there is a natural pro-social bias in language, founded in its function as facilitator of group socialization. Hence, there are fewer words dedicated to negative affect and more descriptors dedicated to sociability (Mehrabian, 1971).

Radd (1994) observed significant differences in word-class frequency of personality descriptors for five languages including American English, Hungarian, Dutch, German, and Italian, imposing serious restrictions upon comparisons between sets of personality descriptive expressions. Such cross-cultural examination has led to some question about the labeling of certain factors with the concern that there is poor consensus on the existence of some factors and possible exclusion of viable dimensions (such as humility) (Fehringer, n.d.).

Furthermore, Cattell's Sixteen Personality Factor Model has been greatly criticized because of the inability of other researchers to replicate his findings. There were undoubtedly mathematical errors discovered in Cattell's early factor analysis resulting in skewed data, thus the inability to replicate (Digman, 1996; Fehringer, n.d.). However, the hierarchical structure of the 16PF has been confirmed at least partially by Rossier, Meyer de Stadelhofen, and Berthoud (2004).

Another major critique of Cattell's approach included the troubling use of too many factors with Eigen values well under .70. Upon re-examination, Cattell's third study (the female sample) reportedly provided a sound five-factor solution resembling the emergence of the Big Five (Digman, 1996; Johnson, 2017). This solution was later confirmed by multiple researchers and the factors were labeled: Extraversion or Surgency, Agreeableness, Conscientiousness, Emotional Stability, and Intellect or Openness to experience (John, Angleitner, & Ostendorf, 1988).

Interpersonal Circumplex

Elizabeth A. Mahar and Patrick M. Markey

Villanova University

Conceptualization and Structure

The interpersonal circumplex is a two-dimensional model in which various interpersonal qualities can be mapped in a circular space. This structure implies that interpersonal qualities vary along a circular continuum and are oriented by the two primary dimensions of agency (also called dominance, assertiveness, and control) and communion (also called warmth, love, and affiliation). These terms were derived from the work of David Bakan (1966), who suggested that they represented the two basic categories of human existence. Agency refers to the existence of a person as an individual and manifests itself as self-assertion, urge to master, control, and seek status, whereas communion represents the participation of individuals in a larger group of people and is manifested as a desire to belong with others, warmth, cooperation, relatedness, and friendliness.

Although the interpersonal circumplex has gone through a number of slight revisions by various researchers, there tends to be agreement concerning its basic structure. Figure 1 displays the circular ordering of the eight-octant interpersonal qualities presented by Wiggins and colleagues (Wiggins, Trapnell, & Phillips, 1988). By tradition, the octants around the circumplex are given alphabetic names in a counterclockwise direction (e.g. PA, BC, DE, etc.) and can be defined by their angular location ranging from 0° to 360°. In this manner, agency and communion can serve as a kind of Cartesian coordinate system to geometrically locate various interpersonal constructs around the circumplex.

Because of the structure of the interpersonal circumplex, it is possible to use the dimensional axes of agency and communion to classify an individual's interpersonal style by both its angular location and vector length. An individual's angular location serves to categorize a person into one of the eight octants of the circumplex. The vector length corresponds to how far a person falls from the center of the circle, representing the extremity of his or her interpersonal style. This extremity can range from moderate and flexible (i.e. close to the
Figure 1 The interpersonal circumplex.

center of the circle) to extreme and inflexible (i.e. far from the center). The formulas below can be applied in order to compute an individual's angular location and vector length.

$$\text{Angular Location} = \text{arctangent}\left(\text{Zagency} / \text{Zcommunion}\right)$$

$$\text{Vector Length} = \left[\left(\left(\text{Zagency}\right)^2 + \left(\text{Zcommunion}\right)^2\right)\right]^{1/2}$$

Where:
Zagency is the standardized agency score of a given person
Zcommunion is the standardized communion score of a given person

For example, using the above formulas, a fictitious person who is agentic (e.g. Zdominance = 1.0) and communal (e.g. Zcommunion = 1.0) would have a vector length of 1.0 and an angular location of 45°, classifying him or her in the NO octant or as "gregarious-extraverted" (i.e. between 22.5° and 67.5°).

The structure of the interpersonal circumplex presented in the figure implies that interpersonal qualities or traits arranged around the circumplex represent different "blends" of the two dimensions of agency and communion. For example, gregarious-extraverted is depicted as a blend of high agency and high communion, whereas arrogant-calculating is a blend of high agency and low communion. This approach realizes that while some traits may be orthogonal to each other when assessed across individuals (e.g. the orthogonal dimensions of agency and communion, the personality traits within the Five Factor Model, etc.),

they are not isolated entities within individuals. This understanding has been an underlying (although sometimes forgotten) theme in the study of personality since Gordon Allport (1937) defined personality as "the dynamic organization *within* the individual of those psychophysical systems that determine his unique adjustments to his environment" (p. 48; emphasis added). A person who is agentic and communal will likely exhibit different behaviors (e.g. gregariousness) than an individual who is agentic and not communal (e.g. arrogant). This view is similar to Lew Goldberg's (1993) horizontal approach to organizing personality constructs, which stresses the importance of locating personality characteristics in a multidimensional space.

By considering these dimensions together, the interpersonal circumplex also provides a useful elaboration of two factors of the Five Factor Model. Specifically, the two primary dimensions of the interpersonal circumplex represent approximately 45° rotations of the Five Factor dimensions of extraversion and agreeableness. The Five Factor Model and interpersonal circumplex are therefore complementary models of personality; the Five Factor Model provides a framework with which to interpret the circumplex and the interpersonal circumplex provides an elaboration of two factors from the Five Factor Model.

History and Assessment

Harry Stack Sullivan's (1954) interpersonal theory of personality stresses that personality is created and maintained through interpersonal interactions. According to Sullivan, in order to understand people, you must have knowledge of the interpersonal characteristics and techniques they express when interacting with others. In an attempt to operationalize and examine the basic concepts related to Sullivan's Interpersonal Theory, in the 1950s, researchers at the Kaiser Research Group in Oakland, California performed systematic observations of 5,000 individuals (many with psychiatric and medical problems) in social interactions. Based on these observations, the director of psychology research at the Kaiser Foundation, Timothy Leary, published the seminal book *Interpersonal Diagnosis of Personality*, which presented the notion that interpersonal variables are arranged in a circular structure called the "interpersonal circle." This circle consisted of 16 interpersonal variables ordered around the primary dimensions of "dominance-submission" (i.e. agency) and "love-hate" (i.e. communion). In order to assess an individual's location on this circle, members of this research team created the 128 self-report item Interpersonal Check List (ICL).

Around this same time, in 1954, Louis Guttman coined the term "circumplex" in order to describe "a system of variables which has a circular law of order" (p.325). Although Guttman did not discuss interpersonal variables in this paper (he focused mostly on mental ability tests), this work, and the developments that followed, provided the foundation for the psychometric properties of circumplex models. Specifically, the structure presented in the figure above implies three basic "rules" concerning the interpersonal qualities around the circumference of the circumplex. First, all interpersonal characteristics around the parameter of the circumplex can be reduced down to different combinations of the two basic dimensions of agency and communion. Second, each interpersonal characteristic is equally spaced from the center of the circle (i.e. each has an equal projection in the two-dimensional space). Finally, the interpersonal characteristics are spaced evenly around the

circle. A circumplex structure also produces predictable intercorrelations among the interpersonal qualities that compose the circle. For example, the correlations among adjacent interpersonal qualities (such as "warm-agreeable" and "gregarious-extraverted") will be larger than the correlations among characteristics more distal from each other (such as "warm-agreeable" and "arrogant-calculating"). Also, the correlations among qualities at right angles are unrelated to each other (such as "warm-agreeable" and "assured-dominant"), and qualities at opposite pose of the diameter are negatively related (such as "warm-agreeable" and "cold-hearted").

The work by Guttman and the advancement of statistical techniques have allowed modern scholars to create interpersonal assessments that better adhere to a circumplex structure than the ICL. By factor-analyzing responses from controls and psychiatric patients, Lorr and McNair developed and validated the circumplex structure of the Interpersonal Behavior Inventory (IBI). The next major step in operationalizing the interpersonal circumplex occurred in 1979 when Jerry Wiggins introduced the 128-item Interpersonal Adjective Scale (IAS), which was followed by a shorter 68-item version called the Revised Interpersonal Adjective Scale (IAS-R). The IAS-R is now the most widely used assessment of the interpersonal circumplex as a measurement of normal variations in interpersonal traits. Recent research shows strong support for the circumplex structure of the IAS-R octant scales and the validity of these scales as assessments of interpersonal octants.

Additional Applications of the Interpersonal Circumplex

In addition to assessing interpersonal traits, the interpersonal circumplex has also been applied to understand various variables such as motivation, values, and behaviors (researchers have recently started using a joystick-tracking device to assess agentic and communal behaviors in real time). In addition to examining these interpersonal variables, scholars have also used the interpersonal circumplex to examine interpersonal problems. Interpersonal problems are traits that may lead to personal distress and prevent a person from functioning appropriately in social relationships. The Inventory of Interpersonal Problems (IIP; Horowitz, Rosenberg, Baer, Ureño, & Villaseñor, 1988) contains 64 self-report items and is composed of eight subscales that are located around a circular structure. Beginning at the top of the circumplex and moving counterclockwise the subscales are: domineering (i.e. too aggressive toward others), vindictive (i.e. wants to get revenge against others), cold (i.e. difficulty feeling close with others), socially avoidant (i.e. hard to socialize with others), nonassertive (i.e. finds it difficult to confront others), exploitable (i.e. taken advantage of by other people), overly nurturing (i.e. tries to please others too much), and intrusive (i.e. has a hard time keeping things private). Unlike other assessments of the interpersonal circumplex, the IIP is best conceptualized as a bifactor model. This model suggests that the covariance among the IIP subscales can be accounted for by a single general factor (overall interpersonal problems) and two specific factors represented by the two primary circumplex axes (i.e. agency and communion). In other words, the IIP circumplex can be used to assess three underling dimensions: overall interpersonal problems, agentic interpersonal problems, and communal interpersonal problems.

The conception of the two-dimensional interpersonal circumplex as a measurement of interpersonal characteristics has been further supported by research examining interpersonal complementarity. The principle of complementarity states that, during social interactions, the interpersonal behaviors of one person tends to elicit or constrain the interpersonal style of the other, and vice versa. Perhaps the most popular definition of complementarity that utilized the interpersonal circumplex is Robert Carson's (1969), which states that complementarity occurs when individuals act similarity in regard to communion (i.e. warm behaviors encourage warm responses, and cold behaviors encourage cold responses) and in an opposite manner in regards to agency (i.e. dominance encourages submission, and submission encourages dominance). For example, if person A acts in an agentic and communal manner (i.e. in a gregarious-extraverted manner), the likely response of person B would be to complement this style of behavior by acting in a non-agentic and non-communal (i.e. in an aloof-introverted manner). Past research using the interpersonal circumplex has tended to support this model, finding that people alter their behaviors in a complementarity manner when interacting with confederates coached to act in a particular style, with naive opposite sex-strangers, romantic couples, friends, and therapists.

Psychodynamic Perspective of Defense Mechanisms

Phebe Cramer

Williams College

The concept of defense mechanism refers to a mental process that occurs outside of awareness. This concept is one of the most important parts of classical psychoanalytic theory. In contemporary theory, the concept has been expanded, and its function has been elaborated. As currently understood, the defense mechanism functions to keep the individual unaware of thoughts or feelings that would arouse anxiety or loss of self-esteem if consciously recognized. Defenses occur as part of normal development, but if used excessively or if age-inappropriate, they may signal the presence of psychopathology.

The idea of a defense mechanism was originally presented by Sigmund Freud (1894), who found that people have the capacity to keep painful thoughts or feelings from becoming conscious. Freud (1895/1966) also noted that defenses may explain symptoms of psychopathology. As his work progressed, Freud focused on the role of instinctual drives for understanding human behavior. At this point, defenses were thought of as a counterforce that prevented the discharge of drives. Several different defense mechanisms were proposed. These were considered to be processes with the function of protecting the person from experiencing excessive anxiety.

The work of Anna Freud (1936) elaborated on the motives for defense use. On the one hand, the pressure for discharge of instinctual drives produces an anxiety signal, which results in the use of a defense mechanism to "ward off" the feeling of instinctual anxiety. Anxiety can also emanate from the violation of external prohibitions (objective anxiety), or it may occur when the dictates of internalized prohibition – i.e. conscience – are violated (super-ego anxiety). In these latter cases, the motive for defense has a different origin, namely, the warding off of feelings of guilt. Fenichel (1945) added to this the idea that defenses protect against threats to security and self-esteem.

A number of different defense mechanisms have been identified. The most frequently occurring include repression, denial, projection, displacement, reaction formation, undoing, rationalization, intellectualization, and sublimation. Research has shown that these defenses develop at different ages (Cramer, 1987). Repression, which may be understood

to underlie all of the other defenses, must thus develop first, at least in some primitive form. Denial is the next defense to develop, and is characteristic of early childhood. It functions by attaching a negative marker – no, not, never – to a thought or feeling, as when the young child says, "I don't care that he got a brand new bicycle." During later childhood and early adolescence, projection becomes a prominent defense. Here, the individual projects, or attributes, his or her own negative thought or feeling onto another person, as when the boy who dislikes his teacher says, "She doesn't like me" – assuming, or course, that this is not actually true. In late adolescence, the defense of identification become prominent. The operation of this defense is different from denial or projection. Rather that ridding the self of unwanted thoughts or feelings, identification functions by taking on, as one's own, the characteristics of another individual. This person is generally someone who is admired and/or seen as stronger. The process of identification in adolescence contributes to the formation of a personal identity. Although not yet demonstrated through research, it seems likely that the other defenses also show a developmental pattern, emerging later in development.

The development of defenses may be considered from two points of view. First, as suggested above, development implies that the use of defenses changes over time, and that there is a chronological ordering of the emergence of different defenses. From this vantage point, defenses may be considered age-, or stage-appropriate. Defenses that develop later in time may be considered "mature." From a second point of view, the defense itself may be considered to develop. In this conception, a defense has its origin in early reflex behaviors which are gradually transformed into voluntary motor behavior, and then internalized into mental operations, much in the way that Piaget (1952) described the development of cognitive operations. In this conception, the relative strength of a defense changes with age, as described earlier.

In order for a defense to be effective, the person using the defense should not be aware of its function. Research evidence has shown that children's understanding of defenses changes with age (Cramer & Brilliant, 2001). Young children (ages 5–6) do not understand the function of denial; they do not "see through" the defense. However, a few years later, as cognitive capacities have increased, the child can figure out that denial is used to avoid emotional upset. At this point, projection replaces denial as the predominant defense. It remains effective as long as its function is not understood.

Measures

There are problems associated with the attempt to measure defense mechanisms. Since defenses are unconscious processes, of which the person is not directly aware, it is logically inconsistent to ask the person to report on these processes.

However, there are methods in use that ask the person to report on their own defense behavior. Some of these methods include questions that have no obvious relationship to a defense, but nevertheless have been shown to correlate with defense use. Advantages of his approach include the ease of test administration and objective scoring, but limitations include the problems association with self-report – self-enhancement, and the actual utilization of defenses when responding to questions about defense use.

Other measures of defenses take a more indirect approach, in which the defense is assessed without the conscious awareness of the person using the defense. In this method, the functioning of the defense may be recognized by an independent observer. For example, clinical interviews provide an open-ended sample of the person's thought processes, in which the use of defenses may be determined (e.g. Vaillant, 1992). Another approach involves the use of methods for which there is no clearly desirable response, such as the Thematic Apperception Test story-telling (Cramer, 2006). In both of these approaches, the use of defenses may be evaluated by a trained observer. The advantage of these methods is that thought processes are expressed freely, without imposed limits. Problems with these approaches include the possibility of subjectivity or rater bias.

Personality

Research has found that the use of defenses is related to personality characteristics. In early adulthood, projection has been found to be associated with low agreeableness, undependability, low conscientiousness, and high neuroticism, whereas the use of identification as a defense has been found to be related to self-confidence, cognitive commitment, and outgoingness. Further, defenses become increasingly important for predicting personality change with increasing age. For example, the use of mature defenses in early adulthood predicts a more positive personality, better psychosocial adjustment, and greater life satisfaction in later life, whereas the use of immature defenses predicts less favorable personality traits, such as neuroticism and disagreeableness.

The relation of defenses to personality also depends on IQ. Thus, for persons with a low IQ, the use of defenses may have a positive effect, being related to positive personality traits; it appears that defenses serve a compensatory purpose. However, use of the same defense by persons with a high IQ has been found to be negatively associated with healthy personality.

Psychopathology

As indicated earlier, the concept of the defense mechanism was linked in early theory to understanding psychopathology. Pathological symptoms were considered to be the manifestation of particular defense mechanisms. Current clinical work and research studies have found that different defenses are associated with different psychiatric diagnoses. For example, projection is associated with the diagnosis of paranoia, acting out is associated with the antisocial personality, and denial is associated with the narcissistic personality disorder (Vaillant, 1994).

Defenses are considered to be pathological when they are used in an overly rigid fashion, occur in too many different situations, distort reality perception, and interfere with adaptive functioning. Also, as indicated above, defenses may be considered to be pathological when they are age-inappropriate. Nevertheless, defenses also function to reduce anxiety and to protect self-esteem. As with other coping mechanisms, defenses may then serve a positive, non-pathological function.

Sex Differences

Psychodynamic theories of sex development have discussed female sexual identity as characterized by a proclivity to focus attention inward toward the interior world, whereas men's sexual identity involves an outward orientation, focusing on the external world. In this case, one would expect that females would be likely to make use of defenses that modify inner thoughts and feelings, such as denial, reaction formation, or turning against the self, even if this results in falsifying external perception. In contrast, it would be expected that males would rely on defenses that place conflict in the external world, such as projection, displacement, or turning against the object, even if this involves falsely attributing inner motivations to that external world.

Interestingly, this sex-based defense use is sometimes determined more by sex orientation than by biological sex. Thus males and females who have a masculine orientation both make strong use of turning against the object. Those who have a feminine orientation, regardless of whether they are biologically male or female, are more likely to use the feminine defenses of reversal and turning against the self. In this case, sex orientation rather than biological sex is the important factor determining defense use. On the other hand, the use of projection has been found to be associated with a masculine orientation in males, but not in females. Here, both biological sex and sex orientation are the determining factors (Cramer, 2006).

Research has also examined sex-based differences in the relation between defense use and personality functioning. The issue here is whether the use of the same defense by males and females has the same implication for their personality. Sex differences occurred most clearly for the use of projection. Men who relied on projection were described by expert observers as being distrustful of others, transferring blame to others, tending to being manipulative and hostile toward others, tending to direct anger inward, and being anxious and depressed. They also were negatively identified with their fathers. In contrast, women who used projection were described as being lively, positive, and extraverted, and did not show the mistrust, blame transfer, and depression found in the men. When criticized, they directed anger outward. They also were positively identified with their mothers. It appears that women who use projection are less likely to experience psychological difficulties. However, men and women who used the defense of denial were characterized in similar ways. They were described as inconsistent, unpredictable, unstable, and anxious. They were also depicted as egotistical, self-centered, and self-indulgent, and their cognitive functioning was portrayed as "fuzzy thinking" (Cramer, 2006).

Delay of Gratification

Jacek Buczny

Vrije Universiteit Amsterdam

What Is It? Conceptualization

Delay of gratification has been studied for more than 50 years now. It is defined as a cognitive and motivational mechanism that leads to the choice of a later or more distant goal when a person is being faced with an immediate reward. Delay of gratification is thus an ability to control an impulse for the sake of a more valued, but postponed, reward. Impulse is associated with immediate pleasure, and is in conflict with delayed gratification. For example, instead of spending for fun some money earned within a particular month, a person can make savings and wait 40 years or longer to use it. Delay of gratification represents one of the regulatory processes; for instance, along with goal-setting abilities, that are responsible for successful self-regulation. Delay of gratification is theoretically different from ego control and conscientiousness concepts, because the theory of gratification delay explains why and how a person persists (or not) in waiting for a reward or achieving the long-term goal (Metcalfe & Mischel, 1999).

How Is It Studied? The Paradigm, Developments, and Major Findings

In classic studies, a child, was asked to choose between a larger reward (e.g. two cookies) that was delayed, and a smaller and an immediate treat (e.g. one cookie). The child was told about two options: (1) that the experimenter would leave for a while and that s/he could wait for the larger treat until the experimenter came back without being called or; (2) that s/he could ring a bell, to request the experimenter to come back, at any moment, in order to receive the smaller reward, but without getting the larger reward. The child was left alone in the room until s/he used the bell, or the experimenter returned. The child did not know how long s/he had to wait, to obtain the larger reward. For example, Mischel and Ebbesen (1970) assumed this experimental situation would build a conflict between the

temptation to stop waiting, to obtain the smaller reward as soon as possible, or continue waiting for the original, larger, more preferred choice. The resolution of the conflict was to call the experimenter as soon as the decision – to take the immediate reward – was made. If the child proceeded to delay, the experimenter returned unexpectedly within 15–25 minutes (Mischel & Ayduk, 2011).

Some of modifications of the classic paradigm were made. Mischel, Ebbesen, and Raskoff Zeiss (1972) tested how distractors (playing with a toy, versus thinking about having fun) influenced the delay when the reward was always visually present. Distractions increased the delay. They also tested how thinking about food rewards and thinking about sad events (anything that a child found to be sad), influenced the delay. They proved that these two distractors decreased waiting time, in comparison to thinking about having fun. In the next modification, Mischel and Baker (1975) showed how the delay could be manipulated depending on the cognitive transformations of rewards. In the first condition, a child was told to focus on how tasty, sweet, or pleasant the marshmallow was, whereas in the second example, s/he was asked to concentrate on physical aspects of the treat. These studies indicated that specific cognitive intervention might greatly affect the dynamics of gratification delay.

Moreover, experiments established cognitive processes that determine successful self-regulation in childhood. Children aged four, who delayed gratification longer than other children at the same age, were described by their parents 10 years later as adolescents who were more academically and socially skilled than their fellows. Additionally, the first group of children (high-delayers) also were able to manage frustration or control their behavior better than the low-delayers. Delaying of gratification was positively related to the Scholastic Aptitude Test when these two groups applied to college. Thus, a relatively unsophisticated situation, proved to be diagnostic for a person's life-achievements. The patterns persisted even in adulthood. So, the paradigm is empirically informative and theoretically intriguing (cf. Metcalfe & Mischel, 1999).

In seeking the underlying mechanism, scientists found that the high-delayers at age four were deliberatively avoiding focusing attention on rewards or were distracting themselves. The self-regulation skills developed throughout childhood, determined the difference between high- and low-delayers in adolescence (Mischel, Shoda, & Rodriguez, 1989).

Delay of gratification also is studied in adult samples. Methods used are: (1) questionnaires (hypothetical choice), (2) discounting tasks (real-life choices), (3) sustained delay tasks in which participants, at the beginning, chose the preferred delayed reward that is obviously worth waiting for. Afterwards, the delay was measured as the time a participant could resist the smaller, immediate, reward in order to obtain the larger, preferred, reward. The last method (4) is a repeated trials delay task that demands a repeated choice between a smaller, but immediate, reward, or a larger, but delayed, one; after the trial, each participant received the actual reward, and could change a previous decision. These four types of delayed gratification tasks were positively and moderately correlated with each other, and positively but slightly correlated with other measures of self-regulation skills (e.g. executive function: goal-oriented processes, working memory, attention, and switching) and informant-report measures (e.g. self-control of impulses; Duckworth & Kern, 2011). Thus, delay of gratification is considered as a different psychological mechanism from executive function. It is therefore suggested that "the optimal measurement

strategy is to include both task and questionnaire measures [...] the composite measure of self-control predicted academic performance better than did any single measure" (Duckworth & Kern, 2011, p. 266).

How Is It Explained? Theoretical Background

Metcalfe and Mischel (1999) developed a conceptual model that explained the mechanism of gratification delay. A dual-process model differentiated between "cool" and "hot" systems. The "cool" system is characterized as: cognitive, complex, reflective, slow, develops late in life, is attenuated by stress, and responsible for control over the self. The "hot" system is considered as emotional, approach- and avoidance-oriented, simple, impulsive, fast, develops early in life, is facilitated by stress, depends on stimulus. Action is a result of the interaction between these two systems that cooperate through (1) "hot spots" that generate reflective, thoughtful, and planned behavior, and (2) "cool nodes" that produce automatic reactions in response towards stimuli. The interactions dynamically determine the self-regulation processes, that result in the ability to persist (or not) in pursuing a long-term goal. The mechanism of these interactions is rooted in parallel processing, working in a network; and the overall effect is experienced by a person or could be observed in a behavior. Specifically, "hot spots" and "cool nodes" are linked to an external reference system. "Hot spots" can be activated also by processes implemented in "cool nodes"; alternatively, "cool nodes" can be turned-on by "hot spots." Willpower is a result of the activity of "cool nodes." The nodes cool down the "hot spots" and make rational, planned, and strategic behavior possible. Psychological distance helps to change personal perspective, and automatically induces effective strategies of emotion regulation (cf. Szczygieł, & Mikolajczak, 2017).

In the first periods of life, the "hot" system is more active, and overrules the "cool" system. The consequence of this imbalance is a higher sensitivity to rewards than punishments in 5-to-6-year-old children (Prencipe, Kesek, Cohen, Lamm, Lewis, & Zelazo, 2011), and that could explain increasing obesity in children. Metcalfe and Mischel (1999) claimed that their framework explained why people failed in regulating their emotions. These failures could be described as deficits of will. For instance, when an emotion is strong, and a person is focused on stimuli that provoke this emotion, it is highly possible the person would act impulsively. Nowadays, the important question is how the will could be trained, and how metacognitive knowledge develops.

What Is the Biological Mechanism? Neurocognitive Perspective

One of the most important recent findings was published by Casey et al. (2011) who studied participants examined by Mischel and colleagues 40 years before. They found that high-delayers revealed much better inhibitory control than the low-delayers, especially in tasks activating the "hot" system. Second, the studies sought to find differences in brain activity in regions associated with cognitive control, and sensitivity to reward, between high- and

low-delayers. Whereas the "hot" system includes deep brain structures (e.g. ventral striatum), the "cool" system involves the prefrontal cortex. Moreover, the activity of these two brain systems in response to "stop signals" suggesting control or delay was different in these two groups, who in early childhood were characterized as high- and low- delayers. Brain regions associated with sensitivity to rewards were more active in low-delayers, but regions involved in cognitive control and rational decision-making were more active in high-delayers. As delay of gratification seems to be an important part of human life, neuro-imaging studies prove that the ability to delay has biological foundations (Bar, 2010).

How It Can be Developed? Future Directions

As Duckworth, Tsukayama, and Kirby (2013) showed, delay of gratification predicts life outcomes because it diagnoses the ability to self-regulate, rather than other cognitive skills (i.e. intelligence) or reward-driven actions. The delay tasks are better measures of the ability to regulate behavior when confronted with frustrating exercises, because they are less biased than questionnaires. Future studies on self-regulation should take that into account.

A problem for future studies is "What kind of treat?" can be used to examine the delay of gratification in adults. Recent studies (van Koningsbruggen, Hartmann, Eden, & Veling, 2017) suggest that social media can be a good area in which to study the mechanism of delay, because of its popularity and addictive nature (e.g. Błachnio, Przepiorka, & Pantic, 2016).

Extraversion – Introversion

Deanna L. Walker

Western University

The Extraversion-Introversion Dimension: Overview

In considering the extraversion-introversion personality dimension, think of two contrasting people in your graduating class. One of those people enjoys attending all of the class parties, is known for having lots of friends, and is open to seeking out new experiences that offer a thrilling lifestyle. This person is energetic, a leader in most domains, and is very happy with their life. In contrast, is another person who tends to stay away from the class parties and who is instead happiest when quietly staying home with a good book. This second person may have a few close friends, but tends to be more comfortable within their organized and routine lifestyle.

When reflecting on these two contrasting individuals, we can identify them as falling on opposite ends of the Extraversion-Introversion personality dimension. Extraversion is composed of both interpersonal and temperamental components. The interpersonal characteristics of extraversion reflect the most common representation of typical extraverted behaviors, including sociability and assertiveness. This social component is a key feature of extraversion, incorporating extraverts' impact on their social environments as a defining characteristic of the trait. The temperamental characteristics of extraversion reflect increased activity level and positive affect. Thus, when considering the extraversion-introversion dimension, an extravert is typically someone who is more outgoing, talkative, social, and energized, similar to the first-person in the example above. In contrast, an introvert is typically someone who is more reserved, quiet, and passive, similar to the second person in the example above.

Development of the Extraversion-Introversion Dimensions

Carl Jung first ignited the idea of extraversion with his conceptualization of extraversion and introversion as two separate types of people. Jung identified extraverts as having a

focus on the outer world, directing an *outward* flow of personal energy to the social environment. In contrast, he identified introverts as having a focus on the inner mental world, directing an *inward* flow of personal energy focused on internal factors. Although the extraversion-introversion dimension has greatly evolved since Jung's work, he is given credit for coining the terms "extraversion" and "introversion." Building upon this initial work, two of the key researchers to theoretically advance the theory of extraversion-introversion as a personality dimension were Hans Eysenck and Jeffrey Gray.

Hans Eysenck (Eysenck & Eysenck, 1985) conceptualized a hierarchical personality model based on traits that he believed to be highly heritable, and psychophysiologically rooted. To characterize extraversion, Eysenck theorized the concepts of excitation and inhibition in relation to personality and behavior. Within his model of personality, he focused on the three dimensions of extraversion-introversion (E), neuroticism-emotional stability (N), and psychoticism (P). Beginning with these three broad traits at the top of the hierarchy, Eysenck posited that each broader trait is characterized by a narrower number of characteristics. For Extraversion, traits such as *sociable*, *active*, *assertive*, and *sensation-seeking* represent covarying factors loading onto the broader E factor. Eysenck then broke this down further into a third level, which he deemed *habitual acts*. For example, someone who is extraverted is more likely to habitually attend many parties, and to seek out new adventures, such as sky-diving or traveling. These habitual behaviors would together load onto the narrower, second-level, characteristics of *sociability* and *sensation seeking*.

Raymond Cattell further expanded upon Eysenck's three factor approach when he developed a list of 16 personality factors derived from a modern factor analysis of lexical approaches. Of these 16 personality factors, five cluster together to form the higher order factor of extraversion, including interpersonal warmth, impulsivity, and boldness. However, with many arguing that a smaller number of factors could hierarchically incorporate the key factors of personality, researchers continued to narrow in on a smaller number of encompassing personality traits.

With this in mind, one of the most common personality taxonomies prominently used to this day is the Five Factor Model of Personality, also referred to as the "Big Five." Derived from factor analysis of the most commonly used words in the English language, five broad traits were established: Extraversion, Agreeableness, Conscientiousness, Emotional Stability, and Openness. Within this model, extraversion is assumed to adopt a hierarchical structure with six lower order facets: warmth, gregariousness, assertiveness, activity, excitement-seeking, and positive affect.

Biological Correlates

The robust presentation of the extraversion-introversion dimension links back to its genetic basis and physiological processes underlying its considerable presentation in cultures all around the world. Undoubtedly, the nature vs. nurture debate is ever prominent in the realm of personality and individual differences. However, by examining heritability estimates of over 25,000 pairs of twins, extraversion yielded a heritability rate of 60%. This high rate of heritability suggests that the genetic component of extraversion is more important than the environmental rearing of extraverted individuals. In other words, it is

highly plausible that we are *genetically wired* to be extraverted, rather than learning extraverted behaviors throughout the course of our development. When considering gender differences in extraversion, women tend to score slightly higher on gregariousness compared to men, and men tend to score slightly higher on assertiveness compared to women; however, these differences are only modest, and overall there are no significant differences for gender along the extraversion-introversion dimension.

To integrate this knowledge of the pervasiveness and heritability of extraversion, Eysenck was a leading force in the research surrounding the biological basis of the extraversion-introversion dimension. With a focus on cortical arousal, Eysenck integrated his model of personality with the theories of physiological excitation and inhibition. More specifically, he proposed that extraverts and introverts possess differing thresholds of excitation and inhibition in their ascending reticular activation system (ARAS), with introverts possessing a lower threshold for arousal compared to extraverts. The ARAS is a feedback look that connects the cortex to the reticular activating system and mediates the body's state of arousal. Extraverts are characterized by lower resting levels of ARAS arousal, thus motivating them to seek out further excitement and stimulating environments to compensate for this understimulation. For example, extraverts engage in sociable, active behaviors as a way of increasing their level of arousal. In contrast, introverts have a higher resting level of ARAS arousal, thus motivating them to avoid situations that offer overstimulation. In other words, introverts engage in quiet, reserved behaviors as a way of maintaining their already heightened level of arousal.

Offering an alternative to Eysenck's research on the ARAS, Jeffrey Gray examined extraverts' sensitivity toward seeking out rewarding stimuli from their environments. Gray (1970) vehemently disagreed with Eysenck's view of arousal as conditioning behavior. As such, he focused more specifically upon physiological processes, including dopaminergic functioning, and proposed the Reinforcement Sensitivity Theory. Within this theory are two primary systems: the behavioral approach system (BAS), and the behavioral inhibition system (BIS). The BAS is linked with approach motivation, whereby it is responsive to rewards and incentives from the outside world. The BIS is linked with avoidance motivation, whereby it is responsive to threat and punishment. Gray posited that people vary on their sensitivity to BIS or BAS. Someone who possesses a highly reactive BAS is more likely to be very sensitive to reward, and more vulnerable to impulsivity and positive emotions, particularly when approaching a goal. On the other hand, someone who possesses a highly reactive BIS is more likely to be vulnerable to unpleasant emotions, including anxiety and sadness. As such, Gray re-characterized the extraversion-introversion dimensions as impulsivity-anxiety. In Figure 1, we see Eysenck's and Gray's contrasting theories of the extraversion-introversion dimension outlined in conjunction with each other.

Personality Correlates

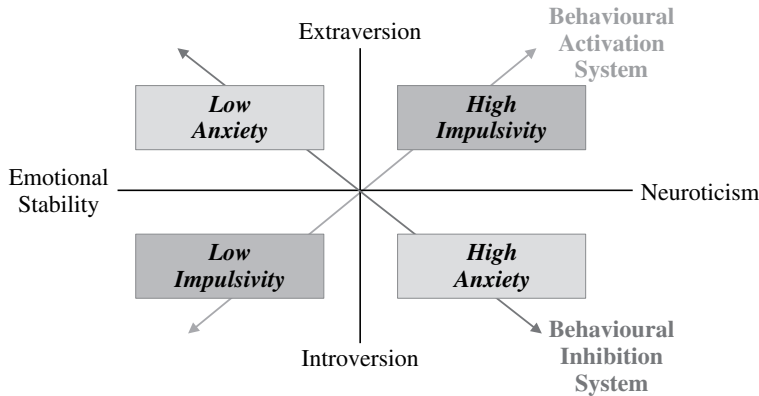
Although Extraversion-Introversion is a robust personality dimension, it is important to recognize the dynamic nature of personality, in that these dimensions do not exist uniquely in a vacuum. In other words, extraversion interacts consistently with other personality correlates, providing implications for life outcomes and individual differences in behavior.


Figure 1 Contrasting Eysenck's dimensions of extraversion-introversion and neuroticism with Gray's dimensions of impulsivity-anxiety (Larsen & Buss, 2018).

Substantial evidence has established that extraverts experience higher levels of positive affect compared to introverts. Additionally, this relationship between extraversion and positive emotions has been replicated across cultures, regardless of personality disposition. While we see that, at its core, extraversion encompasses the core feature of positive affect, additional research has also proposed that extraverts react more positively when presented with positive stimuli.

The relationship between extraversion and positive affect may also be explained by differences in behavioral tendencies. For example, with sociability presenting a key feature of extraversion, researchers have proposed that extraverts not only engage in a greater number of social activities, but they also reap more benefits when engaging in daily social behaviors when compared to introverts. Additionally, extraverts are more likely to view their social interactions, and the world in general, more positively.

Finally, research has examined the link between personality and psychopathology, and has found that extraversion is negatively related to both anxiety and depression. These mental health concerns are often characterized by social withdrawal and low levels of positive affect, which are features relevant to low levels of extraversion. In considering psychopathology as maladaptive extremes of certain personality dispositions, some researchers have identified that very low levels of extraversion (introversion) are linked with social isolation and anhedonia. However, very high levels of extraversion have also been linked with maladaptive risky behaviors such as sexual promiscuity and substance abuse. These concerns may be linked to the greater likelihood for extraverts to seek out and engage in rewarding and highly arousing activities.

Ego Control/Ego Resiliency Theory (ARCH)

Theresa Murzyn

Rutgers University

Ego control and ego resiliency are two related personality characteristics that describe how one regulates one's own emotional and behavioral impulses. Ego control represents one's characteristic degree of impulse restraint. Ego resiliency represents the degree to which one can modify impulse restraint across situations in response to differing situational factors that may either enable or restrict impulse expression.

Jack and Jeanne Block, who developed the ego control and ego resiliency constructs in the 1950s, theorized that individuals differ along a continuum from *overcontrol* to *undercontrol* in their characteristic level of ego control (Block & Block, 1980). *Overcontrollers* tend to excessively inhibit their impulses whereas *undercontrollers* tend to excessively express their impulses. Accordingly, *overcontrollers* are highly conforming, withdrawn during social interactions, and resistant to distraction. They are likely to refrain from outwardly expressing their emotions and excessively delay gratification even when both situational conditions and internal needs would favor gratification. Conversely, *undercontrollers* are nonconforming, distractible, and unable to delay gratification. They have emotional fluctuations and overtly express their emotions even when situations would deem expression inappropriate or disadvantageous.

The Blocks' conceptualization of ego control as maladaptive at either extreme was contrary to theories of related constructs that focused only on the detrimental outcomes of insufficient impulse control. However, impulse control can be excessive and impede experience of life's pleasures. The Blocks therefore argued that "the human goal is to be as undercontrolled as possible and as overcontrolled as necessary" (Block, 2002, p. 183).

The Blocks further theorized that individuals differ along a continuum in their characteristic level of ego resiliency. Those who have a relatively high level of ego resiliency are called *ego resilient*. Though these individuals demonstrate a default level of ego control, they can adaptively modify that level in response to varying situational circumstances. Conversely, those who have low ego resiliency are called *ego brittle*. They have difficulty modifying their default level of ego control across situations and consequently experience

anxiety from their challenge with adaptability. In this context, anxiety means a state of disequilibrium between impulse fulfillment and events outside one's control (Block, 2002).

According to the Blocks' ego theory, an ego brittle individual might not experience anxiety in a situation in which her level of ego control is compatible with situational factors. However, if the situation changed or the ego brittle individual entered a new situation, she could have trouble modifying her degree of ego control to match new situational demands. She would instead continue to inhibit or express her impulses as if stuck in one mode of ego control.

Fittingly, ego brittleness was theorized to coincide with extremely low or high levels of ego control (Block & Block, 1980).

The Blocks conceived of ego control and ego resiliency as measurable characteristics of the *ego* (Block and Haan, 1971). *Ego* is an abstract concept developed by Sigmund Freud and subsequently studied by his followers, including the school of ego psychology, which formed to advance and improve his psychoanalytic theory. *Ego* represents a stable, interactive system of cognitive and behavioral routines called personality structures that develop through life experience and help one regulate internal impulses in relation to external demands. The ego's foremost task is to manage anxiety arising when circumstances lead either internal drives or input from the external world to exceed one's ability to deal with them. One's ego control and ego resiliency, which are characteristics of these structures, indicate how successfully one can regulate the tension between fulfilling one's internal drives and meeting situational demands.

Jack Block championed studying characteristics of ego structures over personality traits, for he argued that traits merely represent a summary of past behaviors. Ego structure characteristics instead determine the set of rules by which people will consistently enact patterns of behavior vis-à-vis situational factors. Investigating characteristics like ego control and ego resiliency would consequently move the focus of personality research beyond differences *between* people to differences *within* people across time and situation to provide a more nuanced understanding of their range of behavior (Block, 2002).

Ego Control and Ego Resiliency Development

As members of the school of ego psychology, the Blocks were interested in the development of ego functions. However, unlike their ego psychology contemporaries who focused solely on theory building, the Blocks sought to empirically derive ego control and ego resiliency scores to investigate their antecedents and test their predictive utility. They sought to track life circumstances that may contribute to or result from certain ego control and ego resiliency levels (Block & Haan, 1971).

The most popular measure from which the Blocks derived ego control and ego resiliency scores was Jack Block's own California Adult Q-set (*CAQ*). This measure features a set of 100 statements that a rater would selectively place into one of nine categories ranging from "very uncharacteristic" to "very characteristic" to represent the degree to which each statement describes a target individual. The resulting set of categorized statements would be called an individual's q-sort profile. To determine individuals' ego undercontrol and ego resiliency scores via the CAQ, separate q-sort profiles of a prototypical ego undercontrolled

person and prototypical ego resilient person were created by clinical psychologists to serve as models of these constructs. Individuals' ego control and ego resiliency scores were calculated as the correlations, or amount of similarity of their q-sort profiles, with each of these prototypical profiles.

Behavioral tendencies associated with different levels of ego control and ego resiliency were assumed to be most evident when individuals were under stress. *Ego resilients* were expected to demonstrate self-assured adaptability whereas *ego brittle* individuals were expected to struggle to adapt. The Blocks believed that the interval encompassing child and adolescent development was considered a stressful period because it imposes age-specific demands on maturing individuals. Observing children over time was expected to reveal behavioral displays of and changes in ego control and ego resiliency. These observations would further reveal any influence of these characteristics on personality development.

The Blocks ran a study to follow participants from early childhood to early adulthood to track changes in their ego control and ego resiliency. To measure ego control and ego resiliency scores at different ages, they asked multiple teachers who knew the participants to rate them on the California Child Q-set (*CCQ*: Block & Block, 1980). They ran various experimental tests on participants as another method to derive ego control and ego resiliency scores. The Blocks further administered questionnaires, parent-child experiments, and interviews to assess parents' child-rearing practices. Q-sort profiles of participants in early childhood predicted their ego control and ego resiliency scores in adolescence, though only male participants' ego resiliency in late adolescence was predicted by their childhood profiles. However, both males and females maintained their relative level of ego control in relation to their peers across childhood and adolescence. This study therefore provided evidence that individual differences in ego control and ego resiliency levels are detectable in behavior and remain somewhat stable across early development. It also revealed that parenting style during early childhood influenced participants' ego control and ego resiliency during adolescence and young adulthood.

Across various studies, theoretically predicted correlates of different ego control and ego resiliency levels emerged. Moreover, when configured with low ego resiliency, both high and low levels of ego control predicted certain behavioral and life outcomes. For example, low ego control combined with low ego resiliency has been associated with delinquent behavior including hard drug use and externalizing problems such as aggression and hyperactivity. Conversely, high ego control combined with low ego resiliency has been associated with internalizing problems such as anxiety, social withdrawal, and depressive symptoms.

High ego resiliency, on the other hand, has been shown to predict children's rate of developing friendship understanding and moral judgment. It can also predict competencies and success in various midlife domains including work attainment, social adjustment, and physical and psychological health (Klohnen, 1996). Fittingly, both children and adults with high ego resiliency have been judged as more popular and demonstrating better social skills. Moreover, a reliable association has been found between ego resiliency and the adaptive poles of all Big Five factors. These findings are consistent with the Blocks' theorized definition of ego resiliency as an ability to flexibly manage one's impulses in response to the demands of various situations.

Personality Types

Block believed that personality types could provide fuller yet more integrated personality profiles than disparate personality traits. He also argued that types could predict more life outcomes. To test his claims, Block pursued a longitudinal study of individuals to track changes in their respective configurations of personality characteristics and corresponding life trends.

Longitudinal studies, in general, were rare at the time of Block's investigation, especially any that tracked personality development from adolescence to adulthood. Many developmental psychologists of the time theorized that personality development progressed similarly for all individuals. Block opposed this view yet further argued that there was a finite number of ways that personality characteristics could be viably and sustainably organized within individuals. Consistent with the Blocks' ego theory, he proposed that persons could be categorized into a small set of personality types, each of which is characterized by a unique configuration of characteristics and pattern of personality characteristic change over time.

As detailed in *Lives Through Time* (Block & Haan, 1971), Block enlisted psychologists to create multiple CAQ profiles per individual from data gathered during adolescence and middle adulthood. He ran a statistical procedure called Q-sort analysis that mathematically identified a set of personality types among the participant sample based on similarities between their profiles. The analysis revealed that each gender exhibited a different variety of personality configurations and configuration changes. Thus, a separate set of personality types was produced for male and female participants. The male typology included *ego resilients*, *vulnerable overcontrollers, unsettled undercontrollers, belated adjusters*, and *anomic extraverts*. The last two types represented individuals who had experienced either a positive or negative change in ego functioning from adolescence to adulthood. The female typology included *female prototypes, cognitive copers, hyperfeminine repressives, dominating narcissists, vulnerable undercontrollers*, and *lonely independents*.

Though other researchers were unable to find this full set of types among other samples, interest in personality typologies grew out of Block's endeavor, especially during the 1990s. Researchers became eager to identify characteristic behaviors of child and adult members of types derived from statistical techniques like that used by Block. They were also curious about personality stability in light of developmental changes.

Whether using participant self-ratings, ratings by teachers and parents, or researcher ratings from behavioral observations, the most reliably identified personality typology has included three categories that are most frequently labeled *resilients, overcontrollers*, and *undercontrollers* (Asendorpf & van Aken, 1999; Caspi & Silva, 1995; Hart et al., 1997; Robins et al., 1996; van Lieshout et al., 1995). These types resemble three of the male types identified in Block's longitudinal study (Block & Haan, 1971). In accordance with the Blocks' ego theory, each of these three types is associated with a unique combination of ego control and ego resiliency levels. The *resilient* type is associated with high ego resiliency and moderate ego control whereas both *overcontrollers* and *undercontrollers* are associated with low ego resiliency. Moreover, while each type's characteristics remain moderately consistent across childhood, individual children can often demonstrate enough change to

be categorized as a different type as they mature (Asendorpf & van Aken, 1999; Hart, Atkins, & Fegley, 2003).

Despite being founded on Block's ego constructs and typological research, the set consisting of *resilients, undercontrollers*, and *overcontrollers* has been commonly referred to as the Asendorpf, Robins, Caspi, and Hart (ARCH) types in honor of the researchers who have used various statistical methods to identify the types among diverse cultural and age samples. Their work has revealed each of the ARCH types to be differentially associated with unique levels of the Big Five traits and competencies in various life domains. *Undercontrollers* and *overcontrollers* have been further associated with unique problem behaviors and psychopathologies (Asendorpf & van Aken, 1999; Hart, Atkins, & Fegley, 2003; Hart et al., 1997; Robins et al., 1996; van Lieshout et al., 1995). Nonetheless, some researchers have raised questions on the validity of the ARCH types for having been unable to be consistently found in multiple samples (Costa et al., 2002).

Continuing Research on Ego Control, Ego Resiliency, and ARCH Typology

While ego control and ego resiliency were originally conceived as two single yet related personality constructs, ego resiliency has been theorized to contain several underlying subcomponents: confident optimism, productive and autonomous activity, interpersonal warmth, and skilled expressiveness (Klohnen, 1996). Further research has been encouraged to elucidate how each of these subcomponents contribute to ego resiliency's association with adaptability and well-being in various life domains.

Some researchers have theorized that the ARCH typology likewise features several subtypes (Asendorpf et al., 2001). A methodological debate has been raised regarding which statistical method may more successfully produce the full collection of subtypes. Other researchers have focused on whether the ARCH types have discrete or fuzzy boundaries, leading membership in any type to vary based on subtle differences in one's scores on ego control, ego resiliency, and Big Five traits. To date, the most thoroughly supported evidence indicates that the ARCH types are best understood as categories with fuzzy boundaries (Asendorpf and van Aken, 1999; Chapman & Goldberg, 2011). According to this description, membership in a type category suggests that one's personality configuration bears greater resemblance to that category's prototype than other categories' prototypes. A prototype perspective acknowledges that those who are classified in the same type category may differ in the degree to which they match the category's prototype. This perspective therefore accounts for inter-individual variability both across and within type categories.

Of greatest import to the future of ARCH research, perhaps, is how the ARCH typology compares to the Big Five factors in predicting outcomes – an issue that echoes Jack Block's argument concerning whether personality types are more informative than traits. Several studies have shown ARCH types to predict personality and life outcomes equally or less successfully than Big Five factors over time (Asendorpf, 2003; Chapman & Goldberg, 2011), though a few studies have found types to better predict outcomes that are further in the future (Hart, Atkins, & Fegley, 2003). Regardless, proponents of the ARCH types and

the typological approach believe personality types remain a valuable tool for concisely communicating interpersonal differences to a general audience (Donnellan & Robins, 2010). That is because the ARCH types, per their design, enable one to describe the collective effects of a configuration of personality characteristics. Variable-centered research necessarily narrows one's focus to the individual effects of each personality trait. Whether these different frames of focus may lead to unique insights on personality is yet unknown.

Emotional Intelligence

Navjot Bhullar and Nicola S. Schutte

University of New England, Australia

Emotional Intelligence

Emotional intelligence is a set of interrelated competencies to adaptively perceive, understand, regulate, and harness emotions in the self and others (e.g. Salovey & Mayer, 1990; Schutte, Malouff, & Bhullar, 2009) and involves the capacity to control and utilize feelings wisely. It is a positive human attribute that is related to a variety of positive life outcomes. Emotional intelligence may be linked to adaptation – the person's adjustment to external circumstances in order to minimize harm and maximize benefits. For example, the emotionally intelligent person is successful in adapting to circumstances that elicit emotion, either through effective regulation of emotion itself, or through application of more general coping and interpersonal skills.

Salovey and Mayer (1990) developed the original theory of emotional intelligence, and the concept was widely popularized by Goleman (1995). Different models of emotional intelligence can be classified into fairly distinct groups termed ability models and mixed models (Neubauer & Freudenthaler, 2005). Ability versus mixed models of emotional intelligence vary considerably regarding the conceptualizations of emotional intelligence and also with respect to the proposed instruments used to measure emotional intelligence (Schutte et al., 2009). Mixed models conceptualize emotional intelligence as typically displayed emotional abilities and use self-report or other-report measures. The ability model conceptualizes emotional intelligence as potential or latent performance and uses performance-based measures of emotional abilities.

The four-branch model of emotional intelligence (Mayer, Salovey, & Caruso, 2004) proposes that emotional intelligence consists of appraisal of emotions in the self and others, expression of emotions, regulation of emotions in the self and others, and utilization of emotions in solving problems. Subsumed under these branches are functions such as verbal and nonverbal appraisal and expression of emotions and using emotions to motivate as part of the utilization of emotions. In line with this conceptualization they developed first the Multifactor Emotional Intelligence Scale (MEIS) and then its successor, the

Mayer-Salovey-Caruso Emotional Intelligence Test (MSCEIT), both maximal performance tests modeled after traditional cognitive ability tests.

Emotional intelligence has also been conceptualized as a trait or typical functioning (Neubauer & Freudenthaler, 2005), similar to personality dimensions such as extraversion, openness to experience, or conscientiousness. A trait conceptualization and measurement of emotional intelligence is one proposed by Bar-On (2000), and operationalized through the EQ-I. Bar-On's (2000) mixed model suggests that emotional intelligence comprises emotional self-awareness as well as various skills or characteristics that may stem from the effective use or regulation of emotions, such as good interpersonal relationships, problem solving, and stress tolerance. Other trait conceptualizations of emotional intelligence are offered by the Assessing Emotions measure developed by Schutte et al. (2009) based on the original model proposed by Salovey and Mayer (1990), and the Trait Meta Mood Scale, also based on this earlier Salovey and Mayer definition.

A trait approach to assessing emotional intelligence draws on self or other reports to gather information regarding the display of emotional intelligence characteristics in daily life. Even though some literature presents ability and trait conceptualizations of emotional intelligence as mutually exclusive alternatives (e.g., Mayer et al., 2004), we believe that both are important and complementary dimensions of adaptive emotional functioning.

Relationship between Emotional Intelligence and Positive Outcomes

Emotional intelligence has received substantial attention in psychology as well as in areas such as education and business. A Google Scholar search in March 2020 showed that over the past years 2,660,000 scholarly works mentioned emotional intelligence.

Emotional intelligence compliments the predictive value of traditional cognitive factors that leave a considerable amount of variance unexplained in educational and organizational outcomes. Further, emotional intelligence has incremental validity in predicting academic and social life outcomes, life satisfaction, and happiness above traditional measures of academic intelligence and personality. Trait emotional intelligence may overlap with a general social effectiveness factor of personality, while ability emotional intelligence seems only moderately associated with this factor (van der Linden et al., 2017).

A meta-analysis by Schutte, Malouff, Thorsteinsson, Bhullar, and Rooke (2007) found significant associations between emotional intelligence and mental, physical and psychosomatic health across studies. A later meta-analysis (Martins, Ramalho, & Morin, 2010) including subsequent studies found similar results.

Emotional intelligence is associated with markers of subjective well-being such as more positive mood, greater life satisfaction and more psychological well-being. Further, emotional intelligence is associated with positive characteristics such as prosocial behavior, empathy, parental warmth, family and peer relations, good quality social interaction, and varied organizationally relevant outcome variables such as job satisfaction, organizational commitment, organizational productivity, and trust.

Higher emotional intelligence is linked with aspects of better psychosocial functioning (Schutte et al., 2007), including intrapersonal factors such as greater optimism and interpersonal factors such as better social relationships. Some of these psychosocial factors, such as more social support and more satisfaction with social support for those with higher emotional intelligence, may serve as buffers to physical illness. Schutte, Palanisamy, and McFarlane (2016) found that higher emotional intelligence was associated with longer telomeres, a biomarker indicating better health and predicting lower mortality rate.

Can Emotional Intelligence be Increased through Training?

Schutte, Malouff, and Thorsteinsson (2013) reviewed studies using emotional intelligence training interventions and provided evidence that such training resulted in increases in emotional intelligence and positive outcomes in important life domains. Typically emotional intelligence training includes psycho-educational elements and application of cognitive behavioral strategies (Schutte et al., 2013).

For example, Kotsou et al. (2011) also found that participants in an emotional intelligence intervention condition reported greater increases in life satisfaction, lower self-reported stress levels, and better cortisol levels as measured by saliva assays. In an organizational study, Groves, McEnrue, and Shen (2008) provided employees with an 11-week training program that presented information on emotional intelligence and modeled the competencies comprising emotional intelligence. They found that those in the training group had significantly higher typical emotional intelligence after the training period than employees in a comparison group.

Future Directions

Future research and applications of emotional intelligence could focus further on group-level emotional intelligence and societal and policy implications of emotional intelligence training interventions. Most emotional intelligence research and application have focused on individuals; however, emotional intelligence can also be conceptualized as a collective or group characteristic that is associated with group performance. More research focusing on collective emotional intelligence at the level of work-groups, organizations, families, and societies would help open further avenues for beneficial applications relating to emotional intelligence.

An example of possible societal and policy implications of emotional intelligence training is provided by Mikolajczak and Van Bellegem (2017). Through assessing associations between participants' emotional intelligence and their health care expenditures, they found that every 1% increase in intrapersonal emotional intelligence corresponded to a 1% decrease in healthcare costs. Coupled with findings regarding the feasibility of increasing emotional intelligence through training, this finding suggests that societal programs aimed at increasing emotional intelligence might have economic benefits as well as enhancing personal well-being.

The utility of high emotional intelligence in various realms of life and endeavors might be further explored. For example, Schlegel, Mehu, van Peer and Scherer (2018) examined the role of emotional intelligence in negotiation outcomes and found that higher emotional intelligence was associated with greater dyadic gains, benefiting both negotiation partners, as well as greater cooperativeness and liking of negotiation partners.

Future research and applications might investigate further the buffering effects of emotional intelligence for individuals in high-stress occupations or for those in especially challenging situations. Research shows that higher emotional intelligence helps in reducing the impact of high work-family conflict on poor mental health among nurses. Such findings have implications both for investigating other populations experiencing stress or challenge and suggest that emotional intelligence training studies involving such populations might be useful.

Erikson's Stages of Psychosocial Development

Yael Gross

Lehigh University

Background

Theory Development

The early stages of Erikson's theory of psychosocial development correspond with the Freudian psychosexual stages of development. More specifically, Erikson's first stage corresponds with the Freudian oral stage, the second stage corresponds with the anal stage, Erikson's third stage corresponds with the phallic stage, the fourth stage corresponds with latency, and Erikson's fifth through eighth stages map onto Freud's genital stage (Franz & Erikson, 1993, 1950; White, 1985). While Freud's theory evaluates an individual's growth and development from infancy through adolescence, Erikson's theory assesses development across the lifespan, from infancy through late adulthood, and also considers cultural factors that may impact advancement through the stages (Erikson, 1993, 1950; Slater, 2003). Furthermore, Erikson focuses on the growth of the ego while Freud focused on the role of the id (Erikson, 1993/1950).

Lifespan Development

Evaluating early child development may offer greater context for assessing later adult psychopathology. Erikson's theory of development explores elements of child development and the psychosocial crises that arise through eight life stages. Erikson's theory takes into account individual readiness for development and societal influences. As such, the stages refer to a developmental phase rather than specific age ranges (Erikson & Erikson, 1998). The eight psychosocial crises are also referred to as tensions between one's syntonic and dystonic tendencies. Through mastery of the syntonic tendencies, the former of each tension couplet, individuals develop a sense of identity, ego integrity, and,

ultimately, fulfillment as contributors to the success of the next generation (Erikson, 1993, 1950; Erikson & Erikson, 1998).

Ego Qualities

Complementary to each psychosocial crisis, Erikson notes a specific quality that is associated with each stage of development. The qualities are Hope, Will, Purpose, Competence, Fidelity, Love, Care, and Wisdom. For example, upon mastery of the first stage of development where an infant builds a sense of trust in their caregiver, the infant gains the foundational quality, or strength, of Hope, which will remain with the individual through the subsequent stages (Erikson & Erikson, 1998). These qualities contribute to the readiness of individuals to transition to the next stage in development, and, more generally, from childhood to adulthood (Erikson & Erikson, 1998).

Erikson's Stages of Psychosocial Development

Basic Trust vs. Basic Mistrust

Erikson's first stage arises from the tension between trust or mistrust that result from interactions between an infant and their caregiver (Erikson, 1993, 1950). When an infant's basic needs of comfort, food, and safety are satisfied, the infant builds a sense of trust in the caregiver. Infants who do not develop a sense of trust may be susceptible to later personality dysfunction and psychopathology; however, these outcomes can be remedied through the reestablishment of a trusting relationship. Finally, Erikson notes that the quality of the infant-caregiver relationship is the most important contributor to the development of trust (Erikson, 1993, 1950).

Autonomy vs. Shame and Doubt

Erikson's second stage explores the development of autonomy or self-sufficiency during toddlerhood. This stage is also referred to as the phase when children learn control and to "hold on and let go" (Erikson, 1993, 1950). With proper caregiver support, young children will develop basic autonomy, such as using the toilet properly. This autonomy will strengthen their feelings of self-confidence and independence, which will enable them to successfully overcome future challenges. Should caregivers fail to foster autonomy or support and protect their child, the child may develop shame in their abilities and lack the confidence to be self-sufficient in later experiences. These early experiences of shame and doubt may also contribute to the development of neuroses as a child attempts to control their environment and reduce the possibility of experiencing feelings of shame. Autonomy is preserved throughout childhood and into adulthood by societal elements, like a judicial system (Erikson, 1993, 1950).

Initiative vs. Guilt

The third stage of Erikson's theory centers around the tension between initiative and guilt during the early childhood years (Erikson, 1993, 1950). Children in this stage are exuberant

with energy and are driven by their initiative to discover by constructing objects and exploring their environment. With proper support from caregivers and teachers, children feel accomplished in their exploration and will continue to produce work beyond this stage. When a child's parents and teacher do not properly guide a child in expressing their excitement, the child may experience feelings of guilt. In adulthood, these feelings may be expressed as denial or through psychosomatic symptoms (Erikson, 1993, 1950).

Industry vs. Inferiority

Erikson's fourth stage of development explores the tension between feelings of industry and inferiority in school-aged children (Erikson, 1993, 1950). Children master this stage through the exploration of their environment and the successful use of tools to produce desirable outcomes. This stage is crucial when developing children's self-confidence, which, when diminished, may result in feelings of inferiority or incompetence, which may persist through future stages of development. At this stage, school is a new setting where children explore and develop. A child's early family experiences have either prepared the child for the expectations within the school, or the school life does not maintain the support offered throughout earlier developmental stages. At this stage, children also develop initial feelings of identity, such as when evaluating their clothing or their cultural group (Erikson, 1993, 1950).

Identity vs. Role Confusion

The fifth stage of Erikson's theory centers on the tension between the concepts of identity and role confusion in adolescence (Erikson, 1993, 1950). From birth through the early school years, children have been exploring their identity and natural talents. In this next stage, adolescents explore their identity, manage the expectations of peers, parents, and society, and also navigate the biological and physical changes associated with puberty. Ego identity is achieved through an adolescent's ability to integrate these separate areas of identity. An adolescent may suffer from role confusion when they are unable to form an identity. Role confusion may cause adolescents to abandon their unique identity and conform to peers' norms in order to reduce feelings of discomfort. Erikson also notes that in this stage of development the adolescent mind is in the transition from the child brain to the adult brain (Erikson, 1993, 1950).

Intimacy vs. Isolation

Erikson's sixth stage of development focuses on the tension between intimacy and isolation during early adulthood (Erikson, 1993, 1950). Individuals enter this stage following the previous stage's exploration of identity with a readiness to engage with others and form close relationships. When young adults avoid the experiences of intimacy they may choose to isolate themselves, especially from those who seem threatening to one's identity. Individuals at this stage are susceptible to feeling both competitiveness and intimacy toward the same person, and navigating these experiences can lead to the development of an ethical sense, a key component of adulthood. Isolation at this stage may lead to psychopathology later in

life, and isolation with a partner at this stage may be a means of avoiding advancement towards the next stage of development (Erikson, 1993, 1950).

Generativity vs. Stagnation

The seventh stage of Erikson's theory focuses on the tension between generativity and stagnation during the transition into adulthood (Erikson, 1993, 1950). While the previous stages have centered on child and young adult development, this stage focuses on the feelings of fulfillment associated with parenting or caring for the next generation. Poor mastery of generativity results in stagnation, or minimal productivity and contribution to the next generation (Erikson, 1993, 1950).

Ego Integrity vs. Despair

Erikson's eighth stage of development explores the tension between ego integrity and despair during older adulthood (Erikson, 1993, 1950). Individuals in this stage reflect on their accomplishments, successes, and challenges. Ego integrity is a state of mind that stems from one's feelings of productivity and meaningfulness in one's lifestyle. Feelings of despair result from regret and, as Erikson (1993, 1950) notes, the feeling that there is "too short [remaining time] for the attempt to start another life and to try out alternate roads to integrity." Those who feel despair tend to have a greater fear of death than those with ego integrity. Erikson (1993, 1950) notes that there are cultural differences in the processes that lead to ego integrity. Bringing the eight stages of development full circle, Erikson (1993, 1950) also notes that infants master of the first stage of development, basic trust vs. basic mistrust, through observing and trusting community leaders who have integrity (Erikson, 1993, 1950).

The Ninth Stage

Joan Erikson, the wife and collaborator of Erik Erikson, offers a ninth stage of development specific to older aged adults. The ninth stage is a reflection of the previous eight stages with the tensions reversed. For example, in this stage, the tension between basic mistrust and basic trust is oriented such that older adults may tend to mistrust their abilities due to the degeneration of physical abilities. Upon reflection of the significance of overcoming the psychosocial crises, Joan notes that "it is important to remember that conflict and tension are sources of growth, strength, and commitment" (Brown & Lowis, 2003; Erikson & Erikson, 1998).

Erikson's Stages Today

Current research aims to further evaluate Erikson's theory. Research by Marcia (2002) evaluated Erikson's theory of development during adulthood. Brown and Lowis (2003) evaluated the ninth stage of Erikson's theory in a group of women. Results support the notion of

an independent ninth stage and further research assessed the correlation between this ninth stage and life satisfaction (Woods & Witte, 1981). Researchers continue to operationalize Erikson's theory and develop qualitative means of measuring the developmental stages, such as through the Erikson Psychosocial Stage Inventory (EPSI; Rosenthal, Gurney & Morre, 1981) and the Measures of Psychosocial Development (Hawley, 1988). Recently, Erikson's theory on the stages from identity in adolescence to intimacy in early adulthood has been further supported through a longitudinal assessment of young adults (Beyers & Seiffge-Krenke, 2010).

Evolutionary Theory of Personality

Heather M. Maranges[1] and Tania A. Reynolds[2]

[1] *Florida State University*
[2] *Indiana University*

Personality is an adaptation. That is to say, personality traits have evolved over time in response to challenges to survival and reproduction, and therefore, were designed to solve adaptive problems frequently encountered by humans' early phylogenetic ancestors. Personality can be understood as a person's characteristic thoughts, emotional responses, and behaviors. Personality traits are patterns of those relatively enduring dispositions that influence behavior across time and situations. Myriad research has supported the contention that personality can be captured by five factors, conceptualized as *openness*, *conscientiousness*, *extraversion*, *agreeableness*, and *neuroticism* (think OCEAN). Openness is associated with the common phrases like "open-minded" or "up to try anything new," and its essence is a divergent cognitive style that seeks novelty and complexity, creatively linking disparate information. Conscientiousness involves orderliness, dutifulness, reliability, and self-control in the pursuit of goals. Extraversion is associated with dominance, sociability, positive emotion, exploratory activity, and reward-seeking behavior. Agreeableness is more or less synonymous with being kind, sympathetic, cooperative, warm, and considerate. Neuroticism can be understood as the tendency to experience negative emotions such as fear, sadness, anger, anxiety, and guilt, as well as the variability in one's emotions over time.

Personality traits are heritable (see Heritability of Personality entry). Heritability is the proportion of phenotypic variance that can be attributed to variance in genetic influence among individuals. A phenotype is the manifested or perceivable traits of an organism (e.g. height, athleticism) and its variance can be broken down into two components: genetic influence and environmental influence. Heritability is the former; it is an estimate of the portion of variance in personality that can be attributed to differences in people's underlying genetic makeup. Heritability is an estimate of genetic influence based on the sampled population (of many individuals). That is, it cannot be estimated from or applied to a single person. Because heritability is estimated from a group of individuals, its estimated proportion depends on the variation among those individuals. The main point, though, is that because traits are heritable, they have been acted upon by natural selection.

Evolution by natural selection is the process by which the heritable characteristics of biological populations change over successive generations. Phenotypic traits that allow organisms (including humans) to successfully respond to challenges in their environment, and promote survival and reproduction, are transmitted to offspring via DNA (genetic information). Traits that are advantageous, or promote the survival and reproduction of organisms, become increasingly prevalent in the population. Likewise, organisms with disadvantageous traits are less likely to survive and reproduce, and these disadvantageous traits are removed from the population. *Adaptations* are evolved phenotypic solutions to recurrent adaptive problems of survival and reproduction; they exist in the present population because they solved problems for ancestral populations. *Natural selection* is therefore a whittling mechanism. Environmental pressures not only include climate, terrain, and predators, but also access to resources such as food, water, cooperative social partners, and fertile mates. Humans' most distinct adaptation is culture, which facilitates cooperation, division of labor, shared resources, safety, and access to the group's stock of knowledge (see Baumeister, Maranges, & Vohs, 2017). *Fitness* is not necessarily physical strength, but rather having traits that facilitate one's survival and reproduction in a given environment. *Inclusive fitness* involves promoting the survival and reproduction of genetic relatives, who also carry copies of the individual's genes. Humans have evolved personality to meet survival and reproduction demands, such that different traits and different levels of traits carry different inclusive fitness advantages.

There are many evolutionary theories of personality, and we group these according to what they explain about personality: (1) why particular personality traits emerged and (2) why there is variation among people in those traits.

Emergence of Specific Traits

The first set of evolutionary explanations of personality answer the question of why personality tends to reduce to the five main factors (OCEAN). That is, when we judge one another's personalities, why do we notice those particular traits and not others? Consider whether someone is often sleepy. Although this might be a trait we notice when interacting with a person, sleepiness is probably not one of the first traits we would use to describe a person. We would, however, be quick to notice and describe our social partners as kind, talkative, or reliable. Personality researchers have forwarded a few explanations as to why the main factors of personality are OCEAN and not others.

Success of the Individual

One theory describing the source of personality factors contends that personality traits emerged from more primal emotional circuits (Montag & Panksepp, 2017). According to this perspective, primal emotions "represent the phylogenetically oldest part of human personality, with that foundation driving behavior and the more cognitive aspects of

personality via a bottom-up affective developmental-learning trajectory." Seven primal emotions have been identified. Four are emotional circuitries for positive emotions: *seeking, lust, care*, and *play*. Three emotional circuitries provide the foundation for negative emotions: *fear, rage/anger*, and *sadness/panic*. Openness arises from seeking, and extraversion from play. Neuroticism rests on all the negative emotional circuits, but especially sadness and fear. Agreeableness emerges from high care and low anger. Conscientiousness, however, is not observed in most mammals and may therefore not be linked to any particular emotional systems. Indeed, associations among the personality factors (except conscientiousness) and primal emotions tend to be consistently strong across individuals from different countries (i.e., the USA, China, Germany) and across gender and age groups. This human-wide pattern grants support for the contention that personality traits emerged from the primal emotional systems of our earlier ancestors.

More than just being by-products of primal emotional systems, the Big Five factors of personality (OCEAN) are functional in and of themselves (MacDonald, 1995). That is, they are motivational systems that push individuals toward fitness-benefiting goals or away from fitness-harming threats. Extraversion, for example, promoted reward-driven goal pursuits. Those who are extraverted are motivated to pursue reproductive opportunities by initiating social interactions with potential mates. Extraverts also pursue social status and power through dominance, which motivates individuals to seek control over others and make group decisions.

Conscientiousness may have evolved as a system that motivated individuals to persist at tasks that were not otherwise intrinsically rewarding. Conscientious individuals are better able to stick to long-term goals by delaying gratification and following through. This tendency, for example, might have facilitated individuals' collecting enough food to last a few days rather than procrastinating to the next meal to forage or hunt. Such preparations would have reduced the dire outcomes resulting from storms or famines. Conscientiousness also involves the trait of dutifulness, suggesting that it may have evolved to motivate individuals to attend to the possibility of punishment. Those who are conscientious are better at following social rules, which helps avoid social exclusion and revenge.

Agreeableness might have evolved to facilitate the formation of supportive and cooperative social bonds. Those who are highly agreeable would feel motivated to spend time with others, share their resources, and provide help to others in times of need. Agreeable individuals would thus better form long-lasting, reliable, and cooperative relationships. These bonds would be advantageous for raising children. Consider for example, how much easier raising a baby is with the care of two cooperative parents compared to the efforts of just one. Social bonds are also useful for gaining access to valuable information and receiving aid when in need or danger.

Neuroticism may have evolved as a threat-detection system, which motivated individuals to attend and respond to cues in the environment signaling danger. Anxiety and worry are major components of neuroticism and can promote preemptive planning and action. Individuals high in neuroticism may have been more likely than those low in neuroticism to over-prepare for a long journey by packing extra food and supplies. Through fear,

neuroticism also promotes avoidance of dangers and risks. A highly neurotic person might be more likely to keep an eye out for approaching predators, avoid handling poisonous snakes, or back away from precipitous cliffs relative to a less neurotic person. Such risk aversion would have prompted individuals to err on the side of caution and reduce the odds of injury or death.

Mate Choice

If personality traits are predictive of individuals' inclusive fitness, then this information should be relevant to mating decisions. That is, when choosing with whom to reproduce, individuals should attend to which potential mates possess qualities that would promote survival or reproductive success. All else equal, individuals would benefit if their offspring possess their mate's advantageous traits because their offspring also possess their own genetic material. Essentially, children are the vehicle for one's own genes as well as the genes of one's mate. Evolutionarily-minded researchers have contended that we discern these personality traits in others because those traits reliably predicted fitness and reproductive success of potential mates in phylogenetically earlier times.

If humans discern these traits in others because the traits indicated likely reproductive success, then these traits should be central components of mate value (Ellis, Simpson, & Campbell, 2002). That is, when assessing who would make a desirable romantic partner, humans should especially emphasize the five personality traits. These traits provide different routes to resources, whether directly or indirectly, such as via attainment of status or supportive bonds.

Openness, which encompasses creativity and curiosity, might have indicated which potential mates would derive novel solutions to group dilemmas or make unique contributions to the group's success, thereby promoting social status. Conscientiousness, on the other hand, might predict which potential mates one could depend on. Because conscientiousness is associated with following through and persistence, it might indicate which potential mates would work hard to obtain status within the group. Furthermore, conscientious individuals tend to adhere to social and moral norms, suggesting that these individuals might be less likely to commit infidelity or abandon a mate.

Through its links to dominance and gregariousness, extraversion might predict which potential mates would be likely to form social alliances and climb the status hierarchy. Agreeableness, which indicates traits such as cooperativeness and empathy would indicate which individuals would be attentive and caring romantic partners and future parents. Indeed, individuals low in agreeableness behave abusively, neglectfully, and selfishly in romantic relationships (Buss, 1991). Neuroticism, which describes a tendency to experience negative affect, would indicate how potential mates would cope with stress. Because neurotics are highly sensitive to threats in their environments, neuroticism might also proxy which individuals would be prone to jealousy. A woman's ability to assess potential jealousy is highly advantageous and consequential because male jealousy is one of the leading causes of homicide among romantic partners (Daly & Wilson, 1988). Thus, from this perspective, discerning potential mates' personality facilitated mate choice to promote inclusive success.

Social Choice

A similar evolutionary theory contends that we discern the five personality traits in one another because those traits reveal information not just about potential mates, but about social partners more broadly (Buss, 1991). That is, humans judge one another on these personality factors because these factors indicate important information about people's probable social behaviors. We notice that someone is kind before we notice that they are fidgety, for example, because kindness is more predictive of someone's future social actions (which are likely to influence our own fitness) than is fidgeting, which is less likely to influence our own fitness.

These perceptions might shift, however, depending upon the social relationship we are considering. Imagine choosing a financial advisor. You might value risk aversion, because you would not want them to make risky decisions with your finances. However, you might be less attuned to the risk aversion level of your neighbors. And indeed, most of the personality descriptions humans use are evaluative, or indicate how well that person would fill various social roles. Essentially, from this perspective, personality evolved as an assessment system to detect differences among individuals in socially-relevant tendencies. Individuals who could accurately assess their group members' general dispositions would make better social decisions. Their discernment would help them choose even-handed leaders, loyal mates, and trustworthy friends.

Hogan (1995) extended this theory of social choice to larger group dynamics. He argued that we assess these traits in one another because this knowledge allowed us to form more successful social groups. He developed a personality inventory based on the Big Five (the Hogan Personality Inventory) that measures the primary characteristics that affect group dynamics (e.g., leadership style, team effectiveness). For example, variation in conscientiousness predicts whether someone is a perfectionist and micro-manager or is willing to take risks. Those with lower or higher levels of conscientiousness would be better suited for some roles over others (e.g., seeking out new territories vs. taking care of children). From this perspective, then, humans evolved to assess each other's personality traits because gauging these allowed more effective role assignment and, hence, group efficiency and effectiveness.

Variation in Personality

The second set of evolutionary theories of personality seeks to explain why individuals vary in personality. That is, why are some individuals highly open while some are quite low in openness? If there were an optimal level of openness, for example, then natural selection should have weeded out those individuals who fell far below or above this point. Consider the fact that nearly every human has two eyes. Apart from mutations or disease, there is essentially no variation across individuals in this trait. Two eyes are optimal. Unlike number of eyes, personality shows substantial variation. Evolutionary theorists have therefore forwarded explanations as to why this level of variance has been maintained in the population.

Assortative Mating

One theory about how variation in personality has been maintained is rooted in kin section and mating. Kin selection describes how organisms promote the survival and reproductive success of other organisms carrying similar genes to themselves. One primary example of kin selection is parenting. Although not explicitly aware of this motivation, parents promote the success of their offspring because those offspring carry copies of each parent's genetic material. By helping their children succeed, parents are promoting the success of their own genes. Kin selection also applies to other family members. The odds that an individual's immediate relative (e.g., sibling) shares similar genes is much higher than the odds a stranger does. Therefore, individuals feel stronger motivations to help and cooperate with their family members, on average, than they do with random strangers.

The theory of kin selection has been applied to how individuals choose mates. When investigating the mating decisions people make, one pattern consistently emerges: people choose mates who are similar to themselves. This phenomenon is called assortative mating and it applies for physical traits (e.g., height, skin color), mental abilities (e.g., IQ), and, yes, personality. This pattern of mate choice makes sense in light of kin selection. If individuals choose mates who have the same traits as themselves, the likelihood that those mates have similar genes (which create those traits) is higher than if individuals choose mates with entirely different traits. When genetically similar mates reproduce, they create an offspring who is even more similar (both in traits and in underlying genes) to each parent. Therefore, by choosing a mate with similar genetic traits, a person enhances his or her genetic relatedness to offspring. Note that this does not necessarily entail choosing mates from the same lineage or family, as that would be maladaptive. Rather, people prefer mates to themselves and therefore clusters of genes similar to their own.

Although assortative mating might have evolved because it enhanced the genetic relatedness of parents to offspring, another consequence is that it maintains genetic variation in traits. Imagine a man who is a 2 (out of 10) in extraversion; he is incredibly introverted. Imagine he assortatively mates with a woman who is also a 2 in extraversion. Their children might be 2s in extraversion, but by shuffling of genetic material, they might also be 1s. Their children, then, would be at the tail end of the distribution of extraversion. Imagine instead that the man had mated with a woman who was an 8 in extraversion (*dis*assortative mating). Their children might be 6s in extraversion, or closer to the mean of extraversion. Assortative mating maintains variation in the population by increasing the number of individuals who fall at the tail ends of a distribution. Indeed, researchers have contended that assortative mating on body weight may be contributing to the recent obesity epidemic. Essentially, those at the high end of the distribution of weight (e.g., obese) are assortatively mating, and producing children who are also at the extreme ends of this distribution.

Trade-Offs

Another evolutionary theory of personality, the Tradeoff Theory of Personality, contends that each personality trait grants both benefits and costs. Differing environments favor higher or lower levels of each trait, maintaining variation. That is, personality traits can be seen as individual reaction norms with different fitness consequences in different environmental niches (Penke, Denissen, & Miller, 2007). Differing environmental demands

produce balancing selection, whereby natural selection maintains genetic variation by selecting both extremes of the trait under different conditions (Penke et al., 2007). When a trait's effect on fitness varies across space or time, significant genetic variation can be maintained in populations.

Nettle (2006) outlined the potential fitness costs and benefits associated with each of the five-factor personality dimensions. Extraversion is adaptive by facilitating exploration of novel aspects of the environment, access to resources through more social partners, and access to mates for reproduction. Indeed, extraverts are more likely to commit infidelity or terminate one relationship for another, which may translate into securing mates of higher quality. Extraversion also produces negative outcomes associated with risk-taking and sensation-seeking, such as serious injury, arrest, and mortality, which impair fitness.

Neuroticism promotes vigilance to threats, such as detecting predators. Anxiety, for example, enhances detection of threatening stimuli by speeding up the reaction to them, interpreting ambiguous stimuli as negative, and locking attention onto them. Further, neuroticism is positively correlated with competitiveness and academic success (for people with good coping strategies). With respect to costs, neuroticism predicts psychiatric disorders (particularly depression and anxiety), impaired physical health (through chronic activation of stress mechanisms), relationship failure, and social isolation.

Openness is associated with socially-valued attributes such as creativity. Indeed, poets and visual artists have higher numbers of sexual partners than controls. However, the unusual thinking style characteristic of openness can lead to unfounded beliefs about the world, from supernatural beliefs to full psychosis. Openness is associated with depression and schizophrenia, and therefore reduced reproductive success.

Conscientiousness also carries both costs and benefits. It predicts health-promoting behaviors, risk avoidance, moral principle, perfectionism, self-control, long-term goal persistence, and consequently, status attainment and longer life expectancy. Conscientious individuals are less likely to engage in delinquency and antisocial behavior. Traits associated with conscientiousness – moral principle, perfectionism, and self-control – however, are linked to eating disorders and obsessive-compulsive personality disorder. These traits may also lead highly conscientious individuals to pass up opportunities that offer immediate rewards (e.g. short-term mating).

Agreeableness is associated with empathy and theory of mind and therefore helps individuals cultivate social support, cooperative relationships, and avoid violent or hostile interactions. Agreeableness is not monolithically adaptive, however. Highly agreeable people can be manipulated, taken advantage of, or outcompeted by cheaters or by those whose trust is conditional. In situations where aggression or conflict is advantageous, agreeable individuals will miss out on opportunities. For example, among modern executives, agreeableness is negatively related to income, status, and creative accomplishment. From this perspective, both higher and lower levels of each personality trait carry costs and benefits, leading to no single optimal value for any trait. If the costs and benefits also vary across space and time (i.e. due to environmental changes), variation will be maintained in the population.

Frequency-Dependence

Some theorists suggest that the extent to which a personality trait is adaptive depends on the frequency of that trait within a population (Maynard Smith, 1998). *Frequency-dependent*

selection is when the prevalence of the trait within the immediate social environment determines the selective advantage of a trait. Some traits are only advantageous when they are relatively rare in the population. Part of this advantage is because competition is most intense among those pursuing the same strategy. For example, if there are two men who want to be the group's carpenter, they will have to compete with one another for that role. If one wants to be the group's carpenter and one wants to be the group's watchdog, there will be less competition between the men.

One example of a frequency-dependent trait is psychopathy, which is characterized by egocentrism, impulsivity, inability to form lasting relationships, superficial charm, and a lack of social emotions (i.e., shame, guilt, empathy). Psychopaths often pursue exploitative mating strategies. For example, psychopathic men are sexually precocious and tend to have many sexual partners, illegitimate children, and failed marriages (i.e., divorces). Psychopathy might be a "cheating" strategy used by those who are unlikely to succeed in tasks that require long-term self-control or cooperation. However, this cheater strategy will only be successful if people fall for it. The more psychopaths in the population, the more people become distrusting. If people are no longer easily duped, the psychopaths will be less successful (Mealey, 1995). The success of psychopaths is therefore frequency-dependent: they are able to successfully exploit others until there are too many other psychopaths in the population.

Because traits usually carry both fitness advantages and disadvantages, some individuals with extremely high levels of seemingly maladaptive traits may benefit from engaging in *high-risk evolutionary strategies*. Genes predisposing people, especially males, to extreme traits will be maintained in a population if those traits have a high reproductive payoff for some, even if they generally reduce fitness in others. Consider risk taking. This may be a generally disadvantageous trait insofar as it increases the risk of injury or death. However, if one male takes extreme risks and subsequently becomes the group leader and reproduces with many women, risk taking will pervade the population. Furthermore, his children will likely have lower levels of risk taking because his genes have been watered down by the mother's. This less extreme level of risk taking may be generally advantageous for his children. Consider bipolar affective disorder. Although bipolar disorder can harm those with severe levels, it is also linked to heightened creativity. Those with milder levels (such as children of those with the full disorder) might reap fitness advantages from the creativity, maintaining genes for the disorder in the population. Likewise, some children with ADHD go on to achieve high levels of success as entrepreneurs, sales people, or entertainment industry powerhouses in adulthood as a result of their heightened energy, drive, and goal-pursuit. Another example is sensation seeking, which is associated with imprisonment. However, sensation seekers who are well socialized are known as creative people, including highly successful scientists, artists, political leaders, and entertainers. From this perspective, some seemingly maladaptive traits can have high payoffs if they promote the reproductive success of a few individuals (often men, because men can potentially sire many more children than women across a lifetime).

Sex Differences in Utility

Men and women faced different selection pressures across human evolution, and consequently there are sex differences in personality (MacDonald, 1995). Women invest more

heavily in reproduction (e.g., pregnancy, childbirth, lactation) than men and have therefore evolved dispositions, such as higher levels of nurturance/love, which facilitate parental investment and care for their relatively dependent newborns. At the extremes of the distribution of that personality dimension is dependency disorder, which is characterized by extreme need for affection and is much more prevalent among women. Men, on the other hand, who can sometimes achieve high reproductive success by investing much less in any one child than women, can benefit from a relatively high-risk strategy that promotes more mating opportunities. Hence, for men, personality attributes including dominance, risk taking, and novelty and sensation seeking can be adaptive. Similarly, the impulsivity that underlies pursuing extramarital and short term mates holds more potential fitness benefits for men than women. Neuroticism, which predisposes individuals to avoid risk and suppress behavioral approach, is a conservative personality reaction to environmental contingencies. Because women are heavily involved in childcare, they may more strongly benefit from risk aversion. Indeed, women tend to be higher in neuroticism than men, on average. Across cultures, women reported themselves to be higher in neuroticism, agreeableness, warmth, and openness to feelings, whereas men were higher in assertiveness and openness to ideas (Costa, Terracciano, & McCrae, 2001).

Environmentally-Selected Variation

Environmental niches, or an organism's immediate ecosystem, shape which phenotypic traits are adaptive, including personality. That is, the immediate context in which individuals find themselves will dictate which level of a personality trait is adaptive. For example, researchers have compared the personalities of Italian coast-dwellers to Italians living nearby on three small islands (Camperio Ciani, Capiluppi, Veronese, & Sartori, 2007). On average, people whose families had lived on the islands for at least 20 generations were much lower in extraversion and openness than both mainlanders and more recent immigrants. This finding suggests that the fitness benefits of extraversion or openness were lower in island locations across history. Perhaps because there are fewer novel individuals with whom to interact on small islands and it is relatively difficult to relocate, extraversion and sociality become less advantageous. Another example is the finding that the 7R allele of DRD4 dopamine gene locus, which is associated with risk taking, extraversion, and novelty seeking, is much more prevalent in European and American populations than in Asian populations. This cultural discrepancy suggests that these traits (and their underlying genetic profiles) were more strongly favored among individuals who migrated to new environments or found themselves in resource-rich conditions (characteristic of the New World).

   Other arguments about environmental niches focus on the affordances granted by culture and an expansive society (Lukaszewski, Gurven, von Rueden, & Schmitt, 2017). Some theorists propose that there is greater personality variation among individuals when the social environment is variegated. That is, complex societies offer many opportunities for specialization, which favors various traits. Consider, for example, a community that subsides mainly off farming. If everyone is farming, there should be relatively consistent selective pressures across individuals. However, in more complex societies, where there are opportunities to fish, hunt, farm, construct shelters, entertain, etc., each niche will create selective advantages for the traits that best serve that role. Hunting might select for strong

and courageous individuals, while entertainment might select for individuals who are open-minded and gregarious.

Life History Theory

Not only is there personality variation within populations of individuals, but also between populations. Rushton (1985) forwarded life history theory, which contends that organisms (including humans) face certain trade-offs. For example, an organism could produce many offspring, but then the organism would not have the time or resources to invest heavily in each offspring. Consider, for example, salmon, who spawn thousands of eggs, simply releasing them into the river water. Now consider elephants, who give birth to one calf around every five years and invest greatly in each calf. Elephant fetuses take up to 22 months to fully develop in utero and when born, can drink up to 10 gallons of their mother's milk a day. Because elephants produce few offspring, they can make substantial investments (e.g. time, protection, calories) in each. These species have responded to a critical reproductive trade-off with quite divergent strategies. Humans must also face the reproductive trade-off of producing *either* many offspring in whom less can be invested or few offspring in whom much can be invested.

Life-history theory, then, describes the series of trade-offs every biological species faces and outlines how the emergent responses will manifest. The answers to these biological trade-offs tend to cluster together, such that they form two ends to a continuum (Figueredo, Vásquez, Brumbach, Sefcek, & Kirsner, 2005). One end is the *k*-strategy, or *fast strategy*, in which organisms invest heavily in maintaining their own bodies (i.e. somatic effort) and promoting the growth and development of their children (i.e. parenting effort). Elephants are examples of a highly *k*-selected species. On the other end of the continuum is the *r*-strategy, or *fast strategy*, in which organisms invest heavily in attracting mates (i.e. mating effort) and producing multiple offspring (i.e. reproductive effort). Salmon are an example of a highly *r*-selected species.

Relative to nearly all species, humans are extremely *k*-selected. Humans take a long time to reach reproductive maturity and invest heavily in their children. Nonetheless, within humans, there is variation among individuals along the *r* to *k* continuum. The environments in which different populations evolved predict where along the continuum populations lie. Environments characterized by a high extrinsic mortality risk select for *r*/fast. Environments where people are at risk of dying by causes that are unpredictable or uncontrollable (such as by the prevalence of infectious diseases) favor quick and voluminous reproduction. If there is a chance the individual could die tomorrow, the individual should not delay reproduction. If there is a chance many of the individual's children could also die, the individual should produce many children to increase the odds that at least one (if not more) survives.

Environments that are predictable, stable, and contain relatively controllable risks of death, on the other hand, select for *k*/slow. Seasonal shifts in temperature and food shortages are predictable and so their consequences are, to some degree, controllable. For example, if a group of individuals knows that winter is approaching, they could work together to prepare by harvesting food and building protective housing. Winter, unlike pathogens, can be prepared for (Rindermann, Woodley, & Stratford, 2012). These controllable environments

would select for traits such as long-term planning and delayed gratification. An individual in a stable, predictable environment is not at high risk of impending death, and can therefore afford to develop slowly before reproducing (i.e., somatic effort). If the individual's children are also not at risk of impending death, the individual can afford to invest heavily in a few children (i.e., parental effort), rather than minimally in many. *K-selected* individuals, as life history theory would predict, delay reproduction, invest heavily in children, and display enhanced executive control, which allows for planful thinking and delayed gratification.

One way that humans responded to controllable environments is by cooperating with one another. *K-selected* individuals tend to prefer and form cooperative, longstanding relationships with each other. To facilitate these cooperative partnerships, they develop many traits that reduce violence and aggression (Figueredo et al., 2018), such as executive control, obedience to social rules, and reduced psychopathy. They also possess traits that facilitate the formation of cooperative social bonds, such as emotional intelligence.

R-selected individuals, on the other hand, were less able to reduce their extrinsic mortality risk (e.g. death by infectious disease) through cooperative social partnerships. Instead, they are more likely to view their fellow social partners as competitors, or as antagonistic to their own goals. *R-selected* individuals tend to be hostile, distrusting, and opportunistic in their social interactions (Figueredo et al., 2018). Because their children are also at an increased risk of dying by external forces, *r-selected* individuals err on the side of caution, by producing more children with more sexual partners, which enhances genetic diversity among offspring. To facilitate these reproductive goals, *r-selected* individuals are relatively open to casual sex, more willing to use violence and coercion to have sex, and do not develop strong emotional attachments to their sexual partners (Gladden, Sisco, & Figueredo, 2008).

The opposing life history strategies have thus contributed to the variation in personality dispositions among humans. Indeed, traits related to these strategies, such as age of reproduction, number of children, executive control, future-oriented thinking, cooperativeness, etc., tend to cluster together within people. Furthermore, these traits are highly heritable; about 65% of the variation among individuals in these overall clusters of traits can be attributed to genetic influence (Figueredo, Vásquez, Brumbach, & Schneider, 2004). This high level of genetic influence indicates that these traits have been selected for over the course of human evolution (Figueredo & Rushton, 2009). Finally, consider that, at their extremes, these life history strategies correspond to differing levels of the Big Five traits. In general, a *k*/slow life history strategy corresponds to higher openness, conscientiousness, extraversion, and agreeableness, but lower levels of neuroticism. A *r*/fast life history strategy, which is characterized by an antisocial schema, is associated with the opposite pattern: lower levels of openness, conscientiousness, extraversion, agreeableness, and higher levels of neuroticism.

Most dictionaries dismiss the entry of "psychoticism" and list it under the psychotic entry as "the state of being psychotic." While this is correct there is so much more that can be said about this term.

While compiling the Eysenck Personality Questionnaire (1978) measuring Extraversion (E) and Neuroticism (N) it became obvious that there was something more that needed adding to the description of a person's personality. This something was deemed a dimension somewhere between psychosis and psychopathy and probably a mixture of both.

However, the task of devising and validating this Psychoticism (P) dimension proved tricky to say the least. Why? For several reasons but mainly because of the nature of the psychological make up of this characteristic (H. J. Eysenck & S. B. G. Eysenck, 1976). While Extraverts are outgoing, sociable, and largely optimistic, Neurotics tend to be anxious and moody, so what were the hallmarks of psychotics or psychopaths?

The answer seemed to be that psychoticism involved endorsing Questionnaire items such as "Do you take much notice of what people think?", "Do you prefer to go your own way rather than act by the rules?" and "Would you take drugs which may have strange or dangerous effects?" In short, psychotics and psychopaths share an aloof independent personality which manifests itself depending on whether it is accompanied by high or low E or N, a brief description of which now follows.

High P low N people are not introspective and will neither care to talk about themselves or, if persuaded to, may well give you false information. This is partly because they do not know themselves at all well and partly because they are uncooperative enough to want to mislead you. They are able, full of drive but convinced they alone are right and others are wrong and this can be a useful frame of mind especially when they ARE right as in the case of genius scientists or artists with an "off beat" creativity which they will not let anyone talk them out of. They are solitary and have difficulties making relationships and there is often a history of casual sex, maybe divorces and a general aloofness.

The high P high N personality is quite different. Here there is guilt set up between the hostile, aggressive P behavior much regretted by the overly sensitive insightful N component.

Hence these people have vast interpersonal problems which disrupt their lives constantly perhaps causing them to seek solutions in drug and/or alcohol addictions. However, they manage to blame others, especially society, for their problems. Adding high E to the high P and high N personality can make for a truly antisocial type of person who likes litigating and may have a criminal record or acquire one in due course.

Interestingly, consider motivation in a hypothetical situation such as the one in which a motorist overtakes on a blind bend. The high E sensation seeker realizes the danger and welcomes the "rush of adrenaline" resulting. The high P scorer, however, would be unaware of the danger and never gives it a thought until it is too late!

There are an almost infinite number of combinations of personality scores but with P high the accent would always be on conflict with others, society, and within themselves. How this manifests itself depends on the other personality scores, intelligence, and possibly the surrounding circumstances.

It has long been noticed that highly creative artists do often display characteristics of psychoticism, even to the point sometimes of madness i.e. psychosis. A detailed discussion of this is given by Eysenck in his 1995 book on Genius. Perhaps those people who lack enough of the characteristic need to withstand criticism of teachers and peers i.e. psychoticism will never pursue their creativity. Or maybe true creativity needs the psychoticism ingredient to become manifested. In support of such considerations, Eysenck (1995) and Simonton (1999) noticed this interesting relationship between the continuum of creativity and psychoticism. Along the continuum of creativity, low levels of psychoticism were associated with an absence of creativity, but increased levels of psychoticism were associated with enhanced creativity.

Some professions clearly favor high P individuals, nursing is one as this needs a cold detached attitude albeit that it sometimes, unfortunately, combines with a cruel streak which the patients may suffer from. Surgeons too need to have that detachment. Active combatants in the Army need a steely attitude and high P indifference to possible harm to oneself or others in battle would be helpful if not essential. The independence of character in high P scorers may be responsible for the retention of original and creative approaches in Science or Art. It could be that their perseverance in spite of (or because of) strong opposition gives them an advantage over high E or high N people who could be predicted to submit to criticism and change their minds more readily.

So psychoticism can be defined by what other personality dimensions accompany it and whether it is an asset in an appropriate profession or a disaster in lifestyle and personal relationships.

Five Factor Model, Facets of

Austin Lee Nichols[1] and Victoria L. Pace[2]

[1] *University of Navarra*
[2] *University of Central Florida*

Overview

Throughout the long history of personality research, experts have traditionally focused on singular traits that were relevant to the phenomenon under investigation. After over 100 years of focusing on hundreds of traits in an effort to explain many diverse behaviors, researchers eventually realized that a lack of focus and common understanding regarding the makeup of one's personality was detrimental to the field and hindering progress toward using personality to explain behavior. Not only did this singular trait-focused approach to personality lack an overarching and agreed upon framework to understand what made humans who they are and different from one another, but it led to the study of many traits with similar conceptual definitions being called and treated as distinct aspects of an individual's personality.

In an attempt to consolidate the personality literature and to bring parsimony to the concept of personality, Costa and McCrae (1992) conceptualized the Five Factor Model (FFM). In general, they conceived the model as the entirety of an individual's personality. That is, the five factors together explained what made one person different from another, and could explain why people behaved in distinct ways without need for any additional traits or factor. The result was a new way of thinking about personality that encompassed all of the previously-examined traits within five distinct factors.

Five Factors

An often-used acronym for remembering the five factors is OCEAN. In that order, the factors are Openness to Experience, Conscientiousness, Extraversion, Agreeableness, and Neuroticism. Openness to Experience often points to those who are creative, open-minded, and intellectual. The opposite would be people who prefer to do things the way

they have always been done and would likely thrive in structured environments. Conscientious people tend to be very organized and responsible. They can be counted on and are known to see things through to the end. In contrast, those low in this factor are often unreliable and even irresponsible. Extraversion, the most popular of the five factors, represents a general tendency to be around other people and to prefer socialization over isolation. In contrast, a more Introverted person avoids large gatherings and is often exhausted after participating in social situations. Agreeableness points to a general tendency to go along with what others want and to avoid asserting oneself when doing so would be in contrast with others' thoughts or desires. Disagreeable people, however, almost prefer to argue their point and have no problem telling you what they think even if it means disagreeing with the beliefs or opinions of others. Finally, Neuroticism represents a general uneasiness and emotionality, especially in times of uncertainty. The opposite end of this continuum, Emotional Stability, is often used to characterize the factor and describes a person who is generally even-keeled and does not let much affect his/her feelings and emotions.

Facets

Perhaps as a result of attempts to fully define the factors of this model and to address questions concerning whether the model is missing important personality characteristics (e.g. a sixth factor), examination of the factors has led to identification of finer-grained components, typically called facets. Although researchers introduced these facets as a way of understanding the components of each factor, the focus of research has often remained on the general factors while neglecting the rich information gleaned from examining the facets. One reason for this is that, similar to times preceding the emergence of the five-factor structure when a plethora of different numbers and conceptualizations of personality factors resulted from early factor analyses, current research has yet to settle on a widely adopted taxonomy of personality facets from the FFM. Named facets vary according to researcher and, especially, according to personality measure.

Efforts toward a Taxonomy of Facets

Facets may be determined rationally by a consideration of the logical composition of a particular factor. However, due to different conceptualizations of the Big Five among researchers and measurement experts, the facets included in each also tend to differ. Factor analytic and other quantitative methods for determining facets are also often employed, but decisions regarding rotation of factors and subjectivity of interpretation remain even in these empirical methods. Therefore, varying numbers and labels of facets exist for each of the five factors. For example, the NEO-PI-R (Costa & McCrae, 1992), probably the most commonly used set of facets, includes 30 facets, whereas Woods and Anderson (2016) developed a list of 26 facets. Additionally, a Warmth facet may be considered part of the Extraversion factor (Costa & McCrae, 1992) or part of Agreeableness (Saucier & Ostendorf, 1999; Woods & Anderson, 2016), depending on the author.

The core of the problem is that each facet, like any factor, can be defined narrowly or broadly and this decision will affect the precision of its measurement and the ability to understand each facet's nature (Soto & John, 2017). Additionally, such decisions will influence convergence with other personality factors or facets and the predictability of behaviors. Much research has shown that convergence of factors across measures may be affected by these conceptual differences (e.g. Pace & Brannick, 2010). As such, currently labeled facets of the same trait may also covary only moderately, when they theoretically should be quite closely related.

Facet-Level Differences in Heritability, Development, and Prediction

Despite the disagreement among scholars, the usefulness of these facets is important to understand. Owing to the unique information added by each, facets allow for enhanced prediction of behavior and important outcomes, beyond the factor level (e.g. Paunonen & Ashton, 2001; Samuel & Widiger, 2008). For example, Reynolds & Clark (2001) found superior predictive ability of personality disorder ratings when using facets of the FFM rather than the domain-level scales. Similarly, work performance dimensions are predicted differentially by individual facets from the same domain scales (Judge, Rodell, Klinger, Simon, & Crawford, 2013).

In fact, it appears that a full understanding of personality development requires examination at the facet level of traits due to variations in age-related changes across facets of the same trait (Soto & John, 2012). Research has shown that heritability also differs by facet (Jang, Livesley, & Vernon, 1996). This is especially true across facets of conscientiousness, revealing a need for differentiation at the facet level when determining genetic vs. environmental effects on personality as well as behavioral outcomes from personality.

Measuring Facets

Due to limitations of time, many five-factor measures do not allow for the measurement of the lower-order facets. However, a large number of measures of FFM factors exist (see Widiger & Trull, 1997, for some comparisons). Many five-factor model measures include sets of facets for each factor (e.g. BFI-2; Soto & John, 2017). Furthermore, many other scales and traits can be classified into facets of the NEO PI-R (e.g. see Appendix A of Judge, Rodell, Klinger, Simon, & Crawford, 2013). Until a consensus exists on how many facets exist and what each of them is, one can only use theory to determine the facets relevant to one's own research and to measure or categorize them effectively.

Future Research

Regardless of the amount of research that has focused on specifying facet-level content of the FFM, more must be done to arrive at a broadly adopted taxonomy of facets. In addition, some still contend that not all personality descriptors are subsumed in the FFM

model and that large gaps in personality coverage, both lexically and in assessment, may exist. For example, there may be clusters of personality-related adjectives that do not seem to be part of the FFM (Saucier & Goldberg, 1998). Perhaps additional research into facets and corresponding modifications to descriptions of each factor will help to resolve this issue of classification.

Following lexical research using circumplex models, it appears that some personality sectors are not well represented by descriptors (Hofstee, De Raad, & Goldberg, 1992). This limits our ability to measure such gaps. Whether these gaps can be considered particularly important to society and research efforts remains a question to be further addressed. Woods and Anderson (2016) proposed personality researchers examine these gaps, attempt to measure these areas, and determine whether they might help to predict work-related criteria. This challenge for better understanding and prediction needs not be limited to work-related criteria, of course. As a field, personality researchers should work together to agree on the conceptualization and measurement of individual differences. Facets provide a very promising way to accomplish this important goal.

Gender Differences in Personality, Evolutionary Perspective on

Keri Ka-Yee Wong and Marie Buda

University of Cambridge

The evolutionary perspective explores the idea of personality as evolved, inherited psychological mechanisms that propagate in response to problems of survival and reproduction faced by our ancestors. These mechanisms interact with sociocultural, physiological, and ecological external stimuli to manifest behavior that we define as character traits or personality. Grounded in the theory of natural selection (Darwin, 1871), the evolutionary perspective conceives that organisms best suited to their environment will go on to survive and reproduce, and through evolution, their genes will proliferate and become the norm. A process of natural selection known as sexual selection describes how personality differences between men and women are expressions of adaptations that emerged from successful mating. Sexual selections include intra-sexual selection, where pressure is exerted within one sex via competition to demonstrate preferred mating characteristics, and epigamic selection, where one sex will exert influence over the other sex by choosing partners with those specific characteristics.

Human Mating Behaviors

Human mating behaviors can be understood temporally as short-term and long-term mating behaviors.

Short-Term Mating Behaviors

Sexual strategies theory (SST; Buss & Schmitt, 1993) describes how sex-distinct behaviors evolved as a result of male and female ancestors having to solve separate adaptive issues in survival and reproduction. Thus, differences in personalities can be understood in terms of the biological sex interacting with the temporal duration of mating for each sex. Take parental investment for example. In women, reproduction incurs an enormous price (i.e. the female

egg is larger and metabolically costlier to produce than the male sperm; fertility is cyclical and age-graded leaving a limited time window for childbirth; carrying offspring for nine months and caring for her child for several years post-birth). In stark contrast, producing offspring is less costly for men (i.e. larger supplies of sperm; can invest less energy in rearing their offspring; larger time window to father children). However, men additionally face the unique problem of paternal uncertainty due to internal female fertilization. SST predicts that gender contrasts in personality traits depends on how each sex interacts with short-term sexual encounters (e.g. temporary affairs, and casual sexual encounters), long-term relationships (e.g. continuing commitment and potential bi-parental investment in children), and how each gender resolves the goals of each type of partnership (cf. Buss & Schmitt, 2016).

Similar to SST, parental investment theory (PIT; Trivers, 1972) states that the more an organism must invest in parental care, the more selective they will be when choosing potential mates. Women are therefore hypothesized to show more hesitancy toward casual sex as they have more parental investment compared with men. Should they engage in a short-term encounter, their priorities would be to secure immediate resources and identify good genes. Contrastingly, the mating opportunity costs hypothesis (Buss, 2015) states that any time invested in parenting is a lost opportunity to mate. Thus, men may bear greater mating opportunity costs, as they could be using the time taking care of their offspring instead of impregnating other females, thereby propagating their genes. In short-term mating, the theory predicts that men, unlike women, will display competitive personalities toward other males (i.e. aggression) in order to secure women. Men's focus will be on increasing partners, minimizing commitment, and identifying sexually accessible women (Buss & Schmitt, 2016).

Long-Term Mating Behaviors

Gender differences are also evident in long-term mating behaviors. Men and women in long-term relationships are thought to resolve many problems of survival and reproduction leveraging on a bi-parental support system that guarantees the survival of their offspring as described by attachment fertility theory (Miller, Pedersen, & Putcha-Bhagavatula, 2005). Based on such a system, men could guarantee greater paternal certainty and women could count on consistent support and resources. Problems with long-term mating were encountered by both genders (e.g. being able to identify a committed partner who is also a good parent), leading to personality traits such as a proclivity toward falling in love or being selective in their mates to develop in both genders, as noted by gender similarities hypothesis (GSH; Hyde, 2005). Although the goals of long-term and short-term mating differ, this notion does not discount the predictions made by SST. The issues of asymmetric parental investment and parental uncertainty still would have persisted in long-term mating, and thus are thought to have still led to sexually differentiated personality traits (Buss, 2015).

Human Sexual Behavior

Human sexual behavior as defined by any activity that induces sexual arousal in solitary, between two persons, or in a group, can be understood through the evolutionary perspective. Gender differences in sexual behavior have been well replicated (Peplau, 2003). Women

self-report desiring fewer sexual partners, taking more time before consenting to sex, being less willing to engage in sex (Buss & Schmitt, 1993), and having a tendency to underestimate men's potential interest in them. Men, on the other hand, report having more sexual fantasies and fantasies involving multiple sexual partners, state a greater attraction toward sexual variety, visit prostitutes more often, and have more extramarital affairs (Buss, 2015), overestimate interest from the opposite sex (Haselton, Nettle, & Andrews, 2015) and compared to women, masturbate more often and earlier in development, which reflects a higher sex drive (Oliver & Hyde, 1993). Finally, when selecting short-term mates, women gravitate toward men with highly masculine looks and displays of resources (e.g. money, status), while men are willing to dramatically lower their standards for casual sex.

Contrastingly, love, romance, and attachment styles do not tend to differ substantially across genders, noted by the GSH. However, men do report falling in love quicker, experience more instances of "love at first sight," and score higher on scales of romanticism compared to women. Conversely, women report being more careful with whom they fall in love with, slower to feel romantically passionate, and more likely to limit their feelings of love to partners who display abilities to provide and protect (i.e. having higher status, intelligence, and resources) (Kenrick et al., 2004). These findings are consistent with SST, which predicts women to be more cautious, and men to be more open with regards to sexual relationships.

Mate Retention Strategies

After successfully establishing a long-term relationship with a desirable partner, one must successful retain their mate. Several sex-specific differences are seen and can be understood through the literature on aggression, jealousy, and parental care.

Aggression

Males have consistently been found to be more aggressive and violent than females, a finding that is replicated in young adolescents and adults. Evolutionarily, males have had to compete with other males for resources, compete for viable fertile mates, and deter sexual infidelity whenever possible. Such competitiveness is evident in young children (Wölfer & Hewstone, 2015). Biologically, men tend to have a shorter index to ring-finger (i.e. 2D:4D ratio) than women, which reflects higher prenatal testosterone levels or greater sensitivity to androgens or both when they were in the mother's womb (cf. Turanovic, Pratt, & Piquero, 2017). Men have also repeatedly been found to have lower resting heart rates than women, which is reflective of men being more of a "sensation seeker" who engages in more antisocial behaviors.

Jealousy

Evolutionarily, jealousy is an important emotional response to deter potential threats to a partnership (e.g. partner infidelity and/or abandonment, mate poaching). While both genders report experiencing jealousy in similar frequencies and intensities, the types of infidelity that provoke maximum feelings of betrayal differ by gender and are those based

on paternal uncertainty. For example, men report greater distress and physiological stress response toward female sexual infidelity, where they risk raising a genetically unrelated child; while women experience the same effect with regard to emotional infidelity, which may lead to partner abandonment and a loss of long-term resources and support toward both her and her offspring. Women may also use other strategies including enhancing their physical appearance to play on men's tendency to seek youthful attractive mates, or purposely induce jealousy in their partners by flirting with members of the opposite sex in order to test their partner's commitment. Alternatively, men are more likely to employ strategies such as displaying resources (e.g. buying gifts), concealing partners when other males are present (e.g. spending all day with partner), submitting to their mate's wishes, and using aggression and violence against any male threats. These findings have most recently been corroborated by cognitive tests (e.g. information search, memory for cues to sexual vs emotional infidelity), physiological measures (e.g. muscle movement) and neuroimaging studies (Buss, 2015).

Parental Care

Gender differences in confidently establishing paternal certainty have said to lead to divergence in personality traits related to parental care. Evolutionarily compared to men, women as the primary caregiver have developed personality traits including empathy, nurturance, and infant facial recognition that are necessarily for the survival of their offspring, as indicated by the primary caretaker hypothesis (Babchuk, Hames, & Thompson, 1985). Under stress, women are more likely to "tend" and soothe offspring and "befriend" members of their social group for mutual defense (Taylor et al., 2000) rather than engage in the adrenaline-based fight-or-flight response in men. Together, these gender-specific personalities have been evolutionarily advantageous for the survival of human offspring.

Evaluation of Evolutionary Perspective of Personality

A summary of some of the strengths and limitations associated with the evolutionary perspective of personality includes the following: crucial in formulating testable hypotheses regarding gender differences, most of which have been confirmed over the years (Buss & Schmitt, 2011). Many reported personality differences have been cross-cultural, thus strengthening the case for their evolutionary heritage (Buss, 2015).

Limitations

It is important to take into consideration the effect sizes of reported differences between men and women. A metasynthesis study of 106 meta-analytic studies on gender differences found only a small effect size for personality differences (d=0.22, ~84% overlap between men and women) (Zell, Krizan, & Teeter, 2015). This highlights greater similarities between the genders than differences. Most findings rely on self-reports which inflate the relationships between constructs; however, studies using other types of testing

(e.g. cognitive, genetics neuroimaging, network analysis) are emerging and corroborate with the original findings.

Conclusion

The evolutionary perspective provides a fundamental understanding and testable framework of the role of gender across a range of behaviors and how it translates to our understanding of personality. This area of research recognizes both differences between genders, but importantly, the similarities as well. However, future studies are still needed before any definitive conclusions regarding gender differences can be made, through triangulating multiple methods, cross-cultural studies, and large population studies.

Contemporary Theories of Gender Identity

Rúben L. Silva and Sara G. Alves

University of Porto

Gender is one of the main axes that guide individuals' place in society, as many interpret and develop their psychological experience in reference to their "womanhood" or "manhood." Both in academic and activist spheres, gender identity is a very important concept that carries decades of thought, debate, research, and practice.

Even nowadays there are plenty of definitions to choose from regarding the concept of gender and others related to it (see Pilcher & Whelehan, 2004 for definitions of essential concepts). The concepts of sex and gender are two that often get mixed up, although there are some key differences between the two. "Sex" refers to the individual's biological sex, such that one is either male or female, in most cases. If this does not happen, when a child is born with ambiguous genitalia, such a child is deemed "intersex" and usually undergoes surgery as an infant to "correct" the situation (there have been campaigns against this in recent years). "Gender," on the other hand, is a culturally charged concept, consisting of the psychological attributes that have been associated in a particular culture with each sex. Although most people think that sex and gender are usually highly correlated, this is not the case; it is not difficult to find a woman that displays psychological features typically associated with men and vice-versa.

Gender identity derives from this last construct, referring to the general sense of belonging to either the masculine gender or the feminine gender and is tied to what it means for a certain culture to be feminine or masculine. Other concepts that usually are mistaken for gender identity are gender roles and gender role attitudes. Gender roles refer to the roles and activities individuals of a certain gender should partake in, according to their culture. Gender role attitudes, on the other hand, consist of the individual's beliefs about the roles and activities for men and women.

Through the evolution and diversity of theory in this domain, the very meaning of gender changed throughout the years. Notably, while initially a biological essentialism dominated that equated sex to gender, contemporary perspectives tend to view gender as a

learned and dynamic dimension of one's identity, increasingly focusing on the cultural influences on its development.

Such is the case of Gender Schema Theory (Bem, 1981), which proposes that children learn the behaviors and personality traits that are linked with either sex (female or male) through socialization, thus creating a network of sex-related associations, or a gender schema. This schema, like all others, is later activated in certain situations to facilitate information processing. The self-concept itself is assimilated into the gender schema, as children learn the attributes that their sex (and thus themselves) should possess. Bem (1981) refers to a schematic selectivity, through which certain attributes are applicable only to one of the two sexes (e.g. "nurturing" is an attribute only applicable to females and "strong" is only applicable to males), making them different not only in degree, but also in kind.

Identity in this perspective follows from the discovery of one's gender that inevitably leads to a self-evaluation in reference to a gender schema, to determine the adequacy of the self in terms of the self's femininity or masculinity, which may affect the individual's self-esteem. Then, the individual may attempt to match their preferences, behaviors, and attributes to those that the gender schema prescribes as being associated with the individual's sex. As such, sex-typed individuals organize their self-concept and behavior around gender, despite how much femininity or masculinity they possess.

This is, thus, a theory of process, focusing on the process of dividing and interpreting the world in terms of two classes contained in the gender schema. Accordingly, the Bem Sex-Role Inventory (BSRI; Bem, 1974) treats masculinity and femininity as two independent dimensions, thus measuring them both with 20 items (personality traits) each. Another 20 filler items are present, leading to a total of 60 items. This inventory allows the classification of individuals as either sex-typed, if the score difference between the masculinity and femininity scale is high, or androgynous if that difference is low.

Ultimately, a sex-typed individual can be either feminine or masculine, depending on which scale the score was highest. This operationalization has led to criticism, as Spence (1985) points out that equaling femininity with expressiveness and masculinity with instrumentality is a theoretical inference that lacks empirical evidence, such that their diagnostic capability is much narrower than Bem claims. It is also a culturally biased view that tends to place gender along a continuum with two extremes, upon which a binary categorization is made that presupposes a certain degree of stability of gender.

In fact, it is noticeable in contemporary perspectives that overcoming the essentialism regarding the formation and nature of gender identity has not meant a reduced importance of its conceptualized stability. Such is the case of the Cognitive-Developmental Theory advanced by Kohlberg (1966), which focuses on the development of the cognitive structures that allow children to attain gender constancy, the knowledge that gender does not change over time. There are three stages in this process (Slaby & Frey, 1975): (1) development of the understanding that one is either a boy or a girl (gender identity), (2) the development of the understanding that this identity does not change over time (gender stability), and (3) the development of the understanding that this identity is not affected by gendered activities or traits (gender consistency).

Throughout this process, children play an active part in constructing the knowledge they possess about gender categories, with a significant impact on their behavior, attitudes, and conformity to gender norms (Kohlberg, 1966). These gender-related behaviors and beliefs

become progressively more rigid (e.g. only girls can wear skirts) until a certain threshold, from which they become more flexible (e.g. both sexes can be whatever they want when they grow up). However, an exact estimation has yet to be made about the precise pinpointing of such threshold, while it cannot be denied in this view that the developing understanding of their gender identity has motivational significance for children.

Other aspects that need to be better defined with empirical evidence consist of the timing and process through which the acquisition of information on gender categories, especially the one the individual belongs to, affects gender-related behavior and attitudes. The Multifactorial Gender Identity Theory (Spence, 1985, 1993) may shed some light on these aspects, while simultaneously showing some promise regarding the tendency of previous perspectives to build upon the binary.

The theory suggests that gender identity derives from multiple gender-related phenomena associated with each other. These phenomena comprise: (1) a global sense of femininity or masculinity, (2) gendered traits (e.g. expressiveness and instrumentality for women and men, respectively), (3) sex roles, attitudes, and attributes, and (4) sexual orientation (Spence & Sawin, 1985). The measurement of each phenomenon must be done separately. Each phenomenon has its own developmental path that differs across individuals and is affected by multiple factors that may or may not be related to gender (Spence, 1985, 1993). These factors and the interaction between them will determine which sex-typed characteristics an individual will develop.

As such, within each gender there is some variability in which gender-congruent qualities are displayed, although that usually does not compromise the often-clear sense of belonging to their own sex an individual has. Thus, a gender identity is developed that remains throughout their life, becoming a fundamental part of the individual's self-image, such that any incongruences (not possessing a stereotypical gender attribute of their own sex or possessing one of the opposite sex) are discounted. While considering the overlooked concept of summary self-perceived gender typicality, Egan and Perry (2001) developed a self-report questionnaire with 10 scales, one of which taps into gender compatibility, a construct that comprises both self-perceived gender typicality and gender contentedness.

While the multifactorial perspective has shown a greater conceptual precision regarding the complexity and dynamics of gender identity formation, to this point gender itself has not been questioned. Contemporarily, the most recent perspectives have marked the paradigm shift from cognitive-developmental perspectives toward a post-structuralist and deconstructionist view that denounces gender as a social artifact. Such is the case of Judith Butler's contribution, a philosopher and a feminist theorist, that set forth the Theory of Performativity (Butler, 1988, 1990). Butler questions the traditional view of gender identity as a stable essence of an individual, or even a developmental product achieved and maintained throughout the lifespan.

That is, one is not born male or female and these are not an immutable part of what defines the individual. Rather, gender is socially constructed through institutionalized actions and roles that are expected and repeated within – and as such, gender is imbued with a person's identity as they are socialized into repeating those same words and actions to fulfill the expectations of their gender, throughout their development. For instance, one is not feminine, delicate, caring, and soft-spoken because of the content of one's genes, but because those are the actions and language patterns that are expected of a woman to be performed, in a specific socio-cultural context.

This perspective has at least two major implications for theory and practice. First, it conceptualizes gender as imbued with social temporality – gender is fulfilled in a specific historical, social, and political context, for which reason gender identity and expression varies across time and different cultures. Second, if gender is socially constructed and not an essence of the human being, it can be critically challenged as being an arbitrary set of iterations that can be rearranged or, ultimately, dropped. This is of particular importance because transforming gender is also acting upon the power structures that hold up a social hierarchy that maintains men in a socially advantaged position over women.

Finally, Butler's contribution can be understood as part of a broader contemporary perspective, Queer Theory, which is rooted in post-structuralism and deconstructionism and provides a critical outlook on interrelated concepts of sex, gender, and desire (Jagose, 1996), based on the work of Foucault (1978). Instead of analyzing how gender is integrated by individuals and shapes their identity, thus impacting on their lives through different psychological processes, post-structuralist views analyze how socially constructed discourses about gender influence individuals' development of the self-concept, impacting on the perpetuation of a specific status quo. A classic example analyzed by Queer perspectives is that of intersex people, and how the power invested in science and medicine has led to the compulsory intervention and reclassification of their bodies (e.g. Butler, 2004; Fausto-Sterling, 2000).

There is still much to be learned concerning gender identity, indeed. The age of identification with a gender is still not known as well as the influence of social, biological, and cognitive factors on its development. The study of this process on intersex children has also been in need of attention. Finally, the integration of the current theories into a broad one, that considers not only purely intra-individual factors but also social and cultural ones on the development of a gender identity seems to be of the utmost importance, in order not to naively reproduce and perpetuate certain patterns of power relations.

Gene-environment Interaction

Karen Nolidin

Swinburne University

The term "nature versus nurture" refers to the interaction between one's genes ("nature") and the environment in which one lives ("nurture") in shaping a person's development and change across their lifespan. Whilst it is acknowledged that people are shaped by their genes and environment, the degree to which each affects various outcomes is not entirely known.

Our genome sets in place the architecture of how we will develop, with genes often referred to as the building blocks of the body. Whilst almost all humans have close to identical genomic sequences, there is some subtle variation. These variations in genes can affect gene expression, such as causing the gene's product to function differently, or to produce more or less of its product.

The "environment" in gene-environment interaction is any non-genetic factor that can cause an outcome. Environmental factors include diet, behavior, exposure to radiation or chemicals, family size, or educational attainment.

These differences in gene expression and environmental factors can result in different phenotypes, which are the expressed characteristic or outcome. Examples of phenotypes include height, weight, hair color, behavior traits, and disease states.

If looking at cancer as a phenotype, we can look at its cause from a genetic or environmental factor. For instance, people with parents who both developed cancer have an increased genetic risk of developing cancer themselves. Yet not all people who carry cancer-related risk alleles develop cancer. Regular smoking is an environmental risk factor for developing cancer, yet not all smokers develop cancer. However, people with an increased genetic risk of developing cancer may be warned to avoid smoking due to the environmental risk that it poses. The combination of increased genetic risk and engaging in behaviors that increase risk may further increase the risk of developing cancer. This example highlights another possible pathway of phenotypic variation that is the gene-environment interaction.

So, while our genetic code provides the template, there are still ways to modify phenotypes through environmental exposure. Across our lifetime the opportunity to make changes remains open for many outcomes. Phenotypes that are under the influence of

gene-environment interactions include tangible phenotypes, such as weight or height, and intangible phenotypes, such as intelligence.

The gene-environment interaction has been widely researched for a range of outcomes. Outcomes such as diseases and medical conditions are generally investigated in terms of presence or absence of disease or signs and symptoms. Those that are generally measured on a continuum rather than presence or absence of trait, such as behavioral or psychological traits, are more difficult to assess unless they are well-defined and conceptualized.

Pedigree, family, and twin design studies have not only demonstrated the heritability of phenotypes, such as intelligence, but also the impact of shared and non-shared exposure to environmental factors on these phenotypes. However, these kinds of studies are unable to identify the genes that may be involved. The development of whole genome sequencing has allowed for the identification of genes, and genome-wide association studies (GWAS) can determine which genes may be behind these phenotypes. Millions of single nucleotide polymorphisms (SNPs) can be sequenced in unrelated individuals, and genetic differences between individuals taken as plausible causes for phenotypic variation. However, variance explained by genotype tends to be low compared to family studies. This gives further credence to the effect that the environment can have on phenotypes.

There are challenges when researching gene-environment interactions on phenotypes. Methodological differences between studies make comparisons difficult, and reproducibility of results is a huge hurdle to overcome in research. Measures may insufficiently capture the environmental factor, or the way the factor was assessed is difficult to replicate. It is also difficult to determine what kind of information is relevant, or how many environmental or genetic factors to take into account. For instance, research suggests that people may be affected by their prenatal environment, from developmental to further ongoing issues later in life. It may also be the case where environmental factors can magnify, nullify, or generally modify phenotypes. Additionally, many factors can be classed as both a phenotype and an environmental factor (e.g. smoking status, educational attainment). Statistical analysis of gene-environment interactions may not appropriately control for potential confounding variables that further affect the interaction (Keller, 2014). With genome-wide association studies, there is a risk of Type I error due to multiple comparisons, so large sample sizes are required. Yet while significant effects may be found as a consequence of increased sample size, the effect of any single SNP allele is small which brings up questions of utility unless SNPs are looked at in functional groups. While GWAS looks at common gene variants, it may be more useful to look into rare variants as they may have a greater impact on phenotypes. Additionally, non-coding regions of DNA are often overlooked, however these may prove just as useful since these include important regions that have actions such as promoter or excision of the genes that follow these regions. There is also the added difficulty of gene-gene interactions and epigenetics. Missing heritability could be partly explained by epigenetics (Ober & Vercelli, 2011), which may give more detail into the biological mechanisms that drive the outcome outside of changes to genetic coding. However, it is even more challenging to research the dynamic interplay between genotype and environmental factors.

Only through increased research can the complexity of gene-environment interactions be more fully understood. With psychological and behavioral traits in particular, there is a need for more collaboration between geneticists, psychologists, and biostatisticians to develop new ways of investigating this field of research.

Goldberg vs Costa/McCrae Five Factors

Timothy J. Kutta, Thomas J. Preston, and Heather M. Maranges

Florida State University

For over 50 years, psychologists have been interested in the construct of personality in order to model which traits people possess and how these are related to variation in domains such as behavior, culture, and well-being. There are two specific models of trait personality that have propelled much of the debate over which are the primary personality factors: Costa and McCrae's model and Goldberg's model. Both center around the idea that five orthogonal personality traits serve as overarching stable dimensions of personality. Nevertheless, they differ in their factor names and the length of each scale item, as well as in the methods by which they were validated, which is considered the primary difference.

Though conceptually similar, one minor difference between these models is the somewhat different naming. Intellect (Goldberg) or Openness to experience (Costa/McCrae) describes people that tend to be intellectually curious and willing to try new things. Conscientious individuals are those that tend to be careful and responsible. Extraverted people tend to be social and outgoing. Agreeableness describes people that are sociable and easy-going. Finally, Neuroticism (Costa/McCrae) or low Emotional Stability (Goldberg) captures the extent to which people tend to be tense and moody or calm and collected.

These five factors were first identified by Donald Fiske in 1949 using data collected by Raymond Cattell. Cattell examined 4,500 English terms that described stable personality traits. Cattell condensed the terms down to 35 clusters of related terms and created rating scales using these clusters, allowing him to examine the correlations of the factors across a number of contexts. He claimed to have found more than a dozen stable personality factors; however, when a more nuanced statistical technique was applied (i.e., orthogonal rotational methods) by Fiske in 1949, a five-factor structure emerged. The lexical hypothesis approach to personality described above assumes that our usage of language will reflect fundamental personality factors. This lexical model was replicated and extended by Lewis Goldberg in 1990. Thus, Goldberg became an advocate for the "Big Five" model using the lexical hypothesis over any potential alternative methods of validation. Critics of

the lexical hypothesis claimed that single words are unable to capture the complexity of human personality and that this approach may yield a simplistic view of personality.

To address these issues, Robert McCrae and Paul Costa developed a second model of trait personality, the "Five Factor Model" (FFM), by comparing the correlations between the factor structure of an 80-item adjective rating task and the ratings on the NEO-Personality Inventory (NEO-PI; McCrae & Costa, 1987). One big difference between the models is the operationalization of the factors: Costa and McCrae used the NEO-Personality Inventory, which originally included Neuroticism, Extroversion, and Openness and later incorporated Agreeableness and Conscientiousness. In addition to the method of validation, the models differ on how the personality factors are operationalized (e.g., warmth is associated with extraversion in the Costa and McCrae model, while it is associated with agreeableness in Goldberg's model) and how they are perceived as interacting with one another (i.e. Goldberg's model does not assume a hierarchical structure to the five factors, whereas Costa and McCrae's does).

The NEO-inventory assesses personality using longer, similarly oriented sentences as items, whereas Goldberg advocated for the single-word-adjective-item approach. Costa and McCrae have found that there is significant overlap when people are asked to rate someone using either single word adjectives or the longer NEO items. In this case, the two models can be viewed as more complementary to one another than in opposition. Critics of these models point to the lack of a theoretical framework underlying the factors. Nevertheless, these models have been foundational to other theoretical frameworks, such as Hogan's socio-analytic theory (Hogan, 1982). Notably, the NEO-PI-R (i.e., the revised NEO-PI) is one of the most prevalent measures used across a number of contexts, including across cultures and to assess abnormal personality traits.

The Big Five and Five Factor Model have proved robust, valid, and reliable, as evidenced by the varied and myriad work that uses these scales and models today. For instance, it has been proposed that trait models of personality may be useful in the classification of maladaptive personality disorders (Krueger, Derringer, Markon, Watson, & Skodol, 2012; Samuel & Widiger, 2008; Thomas et al., 2013). The Five Factor Model has been used to help construct the personality disorders defined in the DSM-V (Krueger & Markon, 2014). Likewise, the PID-5, an inventory used to score the maladaptive personality traits within the DSM-V, has been used to validate the FFM and its application in diagnosing psychopathology (De Fruyt et al., 2013; Thomas et al., 2013). By comparing inventories that measure the five factors of personality and the maladaptive personality factors intended to measure DSM personality disorders, De Fruyt and colleagues (2013) found that both inventories encompass the five factors derived from the FFM.

In addition to aiding in the classification of psychopathology, current trait models of personality have been modified from their original framework in an attempt to bridge the gap between personality psychology and neuroscience. Specifically, recent research has continued to Goldberg's (1999) identification of second-order aspects and third-order facets within the Five Factor Model, allowing for a more thorough investigation of the biological foundations of personality (Allen & DeYoung, 2016; DeYoung, Quilty, & Peterson, 2007).

The five factors appear to be related to brain area volume and white matter integrity in specific regions of the brain (DeYoung et al., 2010; Xu & Potenza, 2012). Specifically, Extraversion correlated with the size of reward information processing regions of the brain

(the medial orbitofrontal cortex); Neuroticism with that of brain areas responsible for negative emotion and the detection of threat and punishment (the right dorsomedial prefrontal cortex and the left medial temporal lobe); Agreeableness with that of brain areas associated with theory of mind (the posterior cingulate cortex and fusiform gyrus); Conscientiousness with brain regions associated with higher cognitive functions such as planning and executive functions (the lateral PFC and middle frontal gyrus); and Openness/Intellect with the right parietal cortex (known for regulating functions such as attention and memory).

With respect to cross-cultural personality research, contradicting results have emerged when personality traits and model structures are compared across multiple cultures (McCrae & Terracciano, 2005; Schmitt, Allik, McCrae, & Benet-Martínez, 2007). For example, McCrae and Terracciano (2005) demonstrated that the Big Five factors mapped onto personalities across 50 cultures. In contrast, Schmitt and colleagues (2007) found significant world region effects for all five personality traits using the Big Five Inventory (BFI). Extraversion was relatively lower in South America, East Asia, and Southeast Asia. Agreeableness and Conscientiousness scores were relatively higher in Africa and lower in East Asia, whereas Neuroticism scores were comparatively lower in Africa and higher in East Asia, South America, and Southern Europe. Openness scores were higher in South America and lower in East Asia and Africa. Likewise, less developed societies such as the Tsimane, a forager group located in Bolivia, show personality structures that drastically differ from those of developed societies (Gurven et al., 2013). Hence, personality traits and their levels may vary significantly from region to region.

In summary, the Big Five and the Five Factor Model proffer five personality factors that are usually referred to as Openness, Conscientiousness, Extraversion, Agreeableness, and Neuroticism. The debate does focus on the number of useful personality factors but rather which method of validation yields the most accurate understanding of personality. These models differ in three ways, the first two of which can be understood as more primary differences: (1) the former was developed via the lexical approach whereas the latter improved upon the prior model by using factor analytics, (2) the former uses single word descriptors while the latter uses sentences as scale items, and (3) their naming scheme. Neuroscience has identified neural correlates of the five factors, and cross-cultural research has underscored how people across the globe are both similar and different. Future research would benefit from clarifying cross-cultural patterns of *reporting* personality and by considering the nuanced differences in linguistic aspects of personality world-wide, two potential sources of the inconsistent international research.

Grit

Lucinda Woodward

Indiana University Southeast

Grit, a personality dimension related to conscientiousness, was first proposed as a unique trait by University of Pennsylvania researcher Angela Duckworth in her 2004 work with West Point Military Cadets to identify ideographic features of high achievers. This landmark study revealed two underlying factors that set apart those cadets who successfully completed their grueling summer-long training program (known as "The Beast"). Those factors were passion (sustained interest over a long period of time) and perseverance (the ability to overcome situations of adversity by being a hard worker). The development of the 12-item Grit Scale in 2004 marked the first systematic attempt to assess passion and perseverance as the underlying features of successful people. Duckworth, Peterson, Matthews, and Kelly (2007) noted that the Grit Scale administered to new West Point indoctrinees was a better predictor of cadet completion of the training program than the whole candidate score initially used to evaluate their application to West Point. Likewise, the authors found that the Grit Scale also predicted achievement across multiple domains.

For example, Duckworth, Peterson, Matthews, and Kelly (2007) found that in a sample of 139 college students, grit was a significant predictor of overall educational achievement (Grade Point Average), controlling for Standardized Achievement Test scores. A second study of 1,218 first-year West Point cadets revealed that grit predicted completion of the rigorous summer training program (the Beast) better than any other predictor. Candidates scoring one standard deviation higher on grit were 60% more likely to complete their summer training than were other cadets. Among 175 2005 Scripps National Spelling Bee finalists, grit and age were significant predictors of participation in the final round, although when verbal IQ was included in the equation, grit was no longer found to be a significant predictor of performance.

In a separate study, Duckworth (2016) described her findings for novice instructors working in disadvantaged schools through the Teach for America program. The authors found that more optimistic teachers tended to manifest higher levels of grit and had higher student achievement scores at the end of the year. She concluded that grit caused effective teachers to continue to search for ways to change their situation for the better, resulting in novel problem solving and higher levels of happiness.

In another multi-study paper, Eskreis-Winkler, Shulman, Beal, and Duckworth (2014) described how grit predicted retention over and above factors such as demographics, intelligence, aptitude, personality, and job tenure across multiple settings. A study of Army special operations forces revealed that, after controlling for intelligence and physical fitness, those ARSOF candidates who scored one standard deviation unit higher in grit had a 32% higher chance of completing their advanced training. Likewise, among 442 sales associates, after controlling for conscientiousness, weeks employed for the company, and years in sales, grit predicted retention among sales representatives better than any other variable. A third study of 4,813 Chicago public school children examined the role of grit in high school graduation. The authors found that after controlling for achievement test scores, conscientiousness, and situational factors, those students scoring one standard deviation unit higher in grit were 21% more likely to complete high school than their peers. Finally, a fourth (online) study of 6,362 adults examined the role of grit in marital longevity. The results indicated that higher grit had a role in relationship maintenance, but only for men, not women.

Definition of Grit

Duckworth (2009) proposed that grit was a personality trait that had its origins in the Big Five Factor of conscientiousness (McCrae & Costa, 1987), but could be cultivated through coaching and education. What is equally important to the definition and underlying factor structure of grit, however, is what sets grit apart from other similar constructs. Notably, grit is not talent per se, although many talented people demonstrate the traits of grit. Talent is an ability we are born with that often requires very little exertion of effort to perform. Duckworth (2016) explained that talent invested with effort results in skill. Skill invested with effort produces achievement. Effortful perseverance, which manifests in this equation two-fold, is one critical aspect of grit.

Grit has also been confused with resilience, or the ability to bounce back after failure or adversity. Although resilience, too, is an important feature in those who achieve greater success in life, grit is much more than a positive response in the face of adversity.

According to Eskreis-Winkler, Shulman, Beal, and Duckworth (2014), achievement is moderately positively correlated to the Big Five Factor conscientiousness, and its underlying facets of self-control, discipline, and low impulsivity. Logically, it might be expected then, that grit would also be related to conscientiousness. But unlike the Big Five Factor, grit describes stamina invested in particular interests and applied long-term effort toward the same higher-order goals. So, grit captures a level of passion not sufficiently reflected by the Big Five facet of conscientiousness.

Finally, grit has occasionally been confused with flow (a state of complete focus and concentration). Flow, unlike grit, however, is the spontaneous and effortless product of sustained practice.

The Grit Scale

Grit has been measured using the Grit Scale (Duckworth, Peterson, Matthews, & Kelly, 2007) a 12-item Likert-style measure that consists of two inter-related subscales assessing

passion and perseverance (r=.45). Subjects rate (on a scale of 1= "not at all like me" to 5= "very much like me") how they think they compare to most people on a series of items that address distractibility, work ethic, focus, diligence, and resilience. Scores range from 0–6 with less than .01% of the population achieving a perfect score. The scale demonstrates good internal consistency (alpha = .85) for the overall scale and for each factor (consistency of interests, alpha = .84 and perseverance of effort, alpha = .78). The measure has good criterion-related validity as a predictor of educational achievement and career consistency in a broad population.

Grit and Aging

Grit has been found to increase with age, so that people in their 60s manifest higher grit than those in their 20s. There are a couple of hypotheses to explain this phenomenon. On one hand, it is possible that grit is a generational effect of the cultural era in which we are raised. Perhaps those who are currently in their 60s endured greater adversity in their youth, which made them stronger and more persistent. Alternatively, our personalities may shift as we get older and we are thrust into new situations that call on us to behave differently, to be more resilient to change. Most likely, shifts in grit over time are the result of an interaction between cultural and individual variables that suggest grit is more plastic than many other personality traits.

Paragons of Grit

The qualitative study of those people who have been deemed fully self-actualized with respect to grit reveals some common characteristics. Duckworth (2016) notes that the four key assets that emerge in high achievers include *interest* or passion in what they do, *practice* and the daily discipline to devote one-self to mastery of a task, *purpose*, or the conviction that one's contributions matter, and *hope* to enable one to continue on when things get difficult. She further asserts that these characteristics are not innate but rather can be acquired through a growth orientation.

Etiology of Grit

The origins of grit are likely multifaceted. Although there is little evidence for a strong environmental basis for grit, there are certainly motivational orientations that seem to have moderate associations with the personality dimension. Specifically, Seligman's correlates of happiness in life – pleasure (hedonic pursuit of positive activity), meaning (engaging in activity that serves a higher, altruistic purpose), and engagement (attention-absorbing activity) – have been found to differentially predict passion and perseverance (Von Culin, Tsukayama, & Duckworth, 2014). Based upon two studies of adult participants in the general population, the authors concluded that pursuit of engagement and meaning were positively correlated to grit, while pursuit of pleasure was negatively correlated to grit. Results are described in order of significance.

The relationship between genetics and grit was examined in a large-scale twin study conducted by Rimfeld, Kovas, Dale, and Plomin (2016). The Grit Scale was administered to 2,321 identical twin pairs at the conclusion of their General Certificate of Secondary Education exams in the United Kingdom. According to the authors, twin analyses of the grit perseverance subscale yielded a heritability estimate of 37% and no evidence of shared environmental influence. Conscientiousness accounted for about 6% of the variance in final grades, and grit added little to the prediction above traditional personality factors. In fact, interest (measured by passion on the Grit Scale) did not predict academic achievement at all. Furthermore, multivariate twin analysis revealed that roughly two-thirds of school achievement was mediated genetically. They concluded that effort, as measured by the Grit Scale, was essentially phenotypically and genetically the same trait as the Big Five Factor conscientiousness.

The conclusion that non-shared environment factors did not predict achievement is in stark contrast to Duckworth's own (2016) assertion that grit can be nurtured through learned optimism or a growth mindset. According to this line of research, children can learn grit through appropriate modeling, coaching, and encouragement.

Perkins-Gough (2013) asserts that non-cognitive character traits, such as grit, may be as important to success as cognitive abilities. This perspective represents a significant swing from the past focus on achievement in schools to a renewed interest in the whole child. Such recent educational reform is represented by a model project in the Upper Darby School District of Pennsylvania, conducted in consult with Angela Duckworth, and intended to increase resilience among the district's 12,400 diverse students. Likewise, companies such as JP Morgan Chase and the Seattle Seahawks franchise have sought to build a culture of grit among employees in order to enhance corporate resilience and achievement.

Just as grit can be fostered in schools and corporations, Duckworth (2016) asserts that grit can be communicated through a balance of supportive and demanding parenting. What Duckworth terms "wise parenting," commonly known as an authoritative parenting style, has been found to produce children who earn higher grades, are more self-reliant, suffer from less anxiety and depression, and are less likely to engage in delinquency. In sum, supportive-respectful parents are more likely to raise children higher in the trait of grit, which leads to greater success as adults.

Hedonic Adaptation

Karynna Okabe-Miyamoto[1] and Julia K. Boehm[2]

[1] *University of California, Riverside*
[2] *Chapman University*

Imagine the excitement you might feel bringing home a new puppy. At first, your puppy is so cute and novel, you make excuses to go home early and play with her. You take pictures of her, take her for walks around the neighborhood, and show her off to friends. However, as time passes, the joy that was once connected with your puppy has slowly diminished. Similarly, if a beloved pet dies unexpectedly, the sadness associated with such a negative experience begins to fade over time. This phenomenon, where an individual's emotional response to positive and negative stimuli lessens with the passage of time, is known as hedonic adaptation or the hedonic treadmill (Frederick & Lowenstein, 1999). Hedonic adaptation involves the natural acclimation to both ongoing life experiences (e.g. being married to the love of one's life) and single life events (e.g. taking one's honeymoon). Hedonic adaptation has evolutionary advantages in that it allows individuals to focus on new stimuli or changes in their surroundings. Remaining in a heightened emotional state for a prolonged period of time, whether positive or negative, could overwhelm an individual and prevent healthy functioning. Hedonic adaptation brings people back to their baseline or pre-event levels of well-being.

The notion of a baseline or set point for one's well-being has a longstanding history in research about happiness (formally known as subjective well-being and shortened here to well-being). Set point theory suggests that a person's well-being – which includes both affective processes like positive and negative emotions, as well as cognitive processes like life satisfaction – stays relatively consistent over the lifespan. Although set points differ for each person and may temporarily increase or decrease due to changes in one's life (e.g. a person feels increased happiness at the start of a relationship or reduced happiness at the end of a relationship), eventually everyone is expected to return to their own personal set point. Evidence for the set point came from a classic study that compared the happiness of lottery winners to non-lottery winners and found no differences (Brickman, Coates, & Janoff-Bulman, 1978). Furthermore, early estimates suggested that life circumstances such as one's level of education, socio-economic status, and marital status accounted for less

than 3% of the variation in well-being (Lykken & Tellegen, 1996). This led researchers to posit that well-being does not change meaningfully over time. Such a conclusion has important implications for individuals who want to become happier – which includes most people – because it suggests that the pursuit of ever-greater happiness is not possible. However, more recent evidence suggests that the set point for well-being can in fact change, especially in the context of meaningful life events.

When individuals experience negative life events, well-being tends to decrease in the period surrounding the event and then rebound. For example, in a prospective longitudinal study, life satisfaction declined to the lowest level in the year preceding a divorce, but began to increase in the years following a divorce (Lucas, 2005). Notably, individuals did not return to their pre-divorce levels of satisfaction after five years, indicating that hedonic adaptation may not be complete after divorce and that the set point may be permanently altered. Similar findings are evident with the death of a spouse or the loss of a job whereby well-being plummets upon the death or job loss, but begins to rebound in the following years (Luhmann, Hofmann, Eid, & Lucas, 2012). Again, however, well-being does not fully recover to pre-event levels, even after several years. In another study, Hernandez and colleagues (2014) found that newly disabled individuals who were married and satisfied with their family life were buffered against the harmful effects of becoming disabled and reported greater life satisfaction over time compared to disabled individuals who were unmarried and dissatisfied with their family life. This suggests that well-being may rebound more quickly (and hedonic adaptation accelerates) when negative life experiences occur in a supportive context.

In contrast to negative life events, evidence for hedonic adaptation to positive life events suggests that adaptation is often complete such that individuals typically adapt to blissful experiences and return to baseline levels of well-being. For example, Luhmann, Hofmann, Eid, & Lucas (2012) found that there was a "honeymoon effect" when individuals married (i.e. well-being improved), but that they quickly adapted to the experience and returned to their pre-marriage levels of well-being. Other research shows that the birth of a child impacts positive emotions and life satisfaction differently. Positive emotions initially decrease after the birth of a child and then slowly return to baseline (Luhmann et al., 2012). In contrast, life satisfaction increases after the birth of a child, but as the hard work of parenting continues, satisfaction returns to baseline levels within two years (Dyrdal & Lucas, 2013). In the case of finding a job after a period of unemployment, positive emotions stay relatively stable over time, while life satisfaction initially declines upon reemployment and then increases in the ensuing year (Luhmann et al., 2012).

As this evidence suggests, the rate and completeness of hedonic adaptation may differ depending on the particular life experience. Moreover, set points for well-being can change due to momentous experiences, especially distressing ones. This indicates that hedonic adaptation may not be inevitable, which is an important modification to the original theory. Another important modification is that set points are not neutral; many people tend to be happy the majority of the time and return to a slightly positive set point (Diener & Diener, 1996). Although set points tend to be positive, three primary factors influence an individual's happiness level: genetics, life circumstances, and intentional activities that involve targeted behaviors to increase happiness (Lyubomirsky, Sheldon, & Schkade, 2005). As suspected by early theorists, a substantial part of the variation in happiness is

genetically-based, but levels of happiness can change. A 17-year study found that although most people had stable levels of well-being across time, 24% showed increases from baseline (Fujita & Diener, 2005). Thus, although there are individual set points in well-being, they are not fixed. Indeed, the affective (i.e. positive and negative emotions) and cognitive (i.e. life satisfaction) components of well-being may also have different set points. In sum, hedonic adaptation is not inevitable and it may be possible to modify its course.

Hedonic adaptation occurs in the context of both positive and negative experiences, but presumably people want to prolong positive feelings and limit negative feelings. Although nobody can escape negative experiences, certain factors like the use of coping strategies can hasten adaptation. Reappraisal, which involves reinterpreting distressing events and emotions, is related to more positive emotions, fewer negative emotions, and better interpersonal functioning compared with suppression, which involves restraining emotional expression (Gross & John, 2003). Individuals who use reappraisal adapt to negative life events more quickly than those who suppress. Additionally, personality characteristics predispose individuals to use specific coping strategies. For example, Bolger and Zuckerman (1995) found that neurotic individuals chose poor coping strategies, which aggravated their suffering and slowed adaptation to distressing experiences. Conversely, optimistic individuals relied on positive coping strategies, which sped adaptation to distressing experiences.

Attention to and variety in experiences are other factors that affect hedonic adaptation. Wilson and Gilbert (2008) theorize that when an individual attends to an event and reacts with positive or negative emotions (e.g. a student feels great because he aced an exam), the next course of action is to explain why the event occurred. If individuals can explain and make sense of the event (e.g. a student put a lot of effort into studying), then they adapt quickly because attending to the event is no longer necessary. However, if the event is unexplainable (e.g. a student has not attended class recently so how did he pass?), individuals will continue to attend because of the surprise, thereby delaying adaptation to the event. Other researchers posit that variety, or the mixture of experiences and emotions, plays a key role in hedonic adaptation. Sheldon and Lyubomirsky (2006) found that people who participated in varied activities (e.g. exercising in the gym Monday and trail running Tuesday) were happier 12 weeks later than people who had a change in a stable circumstance (e.g. moving to a new house). Varying activities enhances novelty and, by definition, it is more difficult to adapt to something that is changing. In contrast, changes in circumstance are subject to adaptation because they are relatively constant.

Feeling gratitude and savoring an experience are other ways to thwart adaptation to positive life experiences. When people express gratitude and relish an experience, they are able to appreciate their circumstances and derive maximal enjoyment, which can delay adaptation to positive events. For example, individuals who were not allowed to eat chocolate (presumably a positive experience) took great pleasure eating chocolate later after regaining access to it (Quoidbach & Dunn, 2012). By contrast, individuals who had constant access to chocolate showed diminished happiness after continuing to eat it. This suggests that enjoyment can be extended if an infrequent experience is savored and appreciated.

Although hedonic adaptation has evolutionary advantages, conscious efforts to reduce the adverse effects of negative life events or prolong the satisfying effects of positive life events can contribute to greater happiness. Furthermore, given that hedonic adaptation is

not inevitable, interventions specifically designed to boost a person's happiness may be effective. Indeed, research demonstrates that interventions can improve well-being in the short-term via straightforward activities such as writing letters of gratitude (Bolier et al., 2013). Knowledge about hedonic adaptation can inform the development and efficacy of such interventions by integrating a variety of positive experiences into the intervention.

Heritability

Heather M. Maranges[1] and Tania A. Reynolds[2]

[1] *Department of Psychology, Florida State University*
[2] *Kinsey Institute, Indiana University*

Every behavioral trait is heritable. This is Turkheimer's first law of behavioral genetics. Personality is no exception. Personality can be understood as a person's characteristic thoughts, emotional responses, and behaviors. Personality traits are patterns of those relatively enduring predispositions that influence our behavior across time and situations. Personality is hereditary, or passed down from one generation to the next via genetic information, and is therefore heritable. Heritability is the proportion of phenotypic variance in an attribute in a population due to genetic variance in that population, and personality traits are heritable. This encyclopedia entry explains what heritability is, briefly describes the methods by which researchers examine the heritability of traits, and details the extent to which particular personality traits are heritable.

Heritability is the proportion of phenotypic variance that can be attributed to variance in genetic influence among individuals. A phenotype is the manifested trait of an individual. This includes height, skin color, and personality. Just as people differ in facial appearance, for example, so too do they differ in personality. Phenotypic variance can thus be broken down into two components: genetic influence and environmental influence. Heritability is the former; it is an estimate of the portion of variance in personality that can be attributed to differences in people's underlying genetic makeup.

It is important to note that heritability is an estimate of genetic influence based on the sampled population (of many individuals); it cannot be estimated from or applied to a single person. Because heritability is estimated from a group of individuals, its estimated proportion is dependent upon the variation among those individuals. For example, if the population sampled differed widely in environments (e.g., some people were from rural Africa, some were from Beijing, China), the proportion of variance in personality attributable to genes would be lower than a population of individuals from relatively homogenous environments. When the sample of individuals is from a homogenous environment, there is less variation in their environments, allowing for more variation in their phenotype to be explained by differences in their genes. When the sampled individuals are from widely

varying environments, on the other hand, this environmental variation diminishes the proportion of their phenotypic differences that can be attributed to genetic influence.

Behavioral genetics is a field of research that uses a variety of methods to estimate heritability. In addition to adoption and family studies, twin studies are a common method. In twin studies, researchers recruit a sample of identical (monozygotic) and fraternal (dizygotic) twins. Monozygotic (MZ) twins result from the fertilization of one egg (i.e., one zygote), which then splits into two developing fetuses. Because the two resulting fetuses were formed from the same egg and sperm, they are genetically identical, sharing 100% of their genes with their co-twin. Dizygotic (DZ) twins result from the independent fertilization of two eggs by two different sperm cells. Like regular siblings, dizygotic twins only share roughly 50% of their genes by common descent. Twins, whether dizygotic or monozygotic, are often raised similarly. That is, they share the same birthday, parents, house, peers, and neighborhood. Through twin studies, researchers capitalize on MZ and DZ twins' similarities in environments and differences in genetic relatedness (100% for MZ, 50% for DZ).

Heritability can be estimated by comparing the phenotypic similarity between MZ and DZ twins. The more a trait is caused by genes, the more similar MZ co-twins should appear in that trait compared to DZ co-twins. This is because MZ twin have 100% of their genes in common, while DZ have only 50% in common. The more a trait is caused by the environment, the more similar both MZ and DZ twins should be on that trait (because both MZ and DZ twins experience relatively similar environments).

The environmental influence on traits can be broken into two subcomponents: shared and non-shared. Shared environment refers to the environmental factors that twins have in common, such as parents, neighborhood quality, household income, etc. Non-shared environment refers to the environmental factors that each co-twin experiences uniquely. For example, one twin (but not the other) may attend summer camp, experience a tumultuous romantic relationship, or attract a supportive best friend.

Theorists and behavioral genetic researchers have published much work demonstrating the extent to which personality attributes in a population can be accounted for by genetic variance. Notably, thousands of genes contribute to specific traits, such that genes combine to influence overall personality, and, through personality's interaction with the social world, happiness and well-being (Weiss, Bates, & Luciano, 2008). Temperament, biologically-based personality tendencies that are conceptualized as broader than specific traits, may be the main aspects of personality that are influenced by genes. Specifically, the broad patterns of activity level, sociability, and emotional stability appear to be highly heritable, as evidenced by a review of behavioral genetic research (Buss & Plomin, 2014).

With respect to specific personality traits, each of the Big Five personality traits has heritability estimates around .5 (Bouchard, 2004). Briefly, myriad research has supported the contention that personality can be captured by five factors, usually conceived as *openness*, *conscientiousness, extraversion, agreeableness*, and *neuroticism*. Openness is associated with the common phrases like "open-minded" or "up to try anything new," and its essence is a divergent cognitive style that seeks novelty and complexity while drawing connection between various pieces of information. Conscientiousness involves orderliness and self-control in the pursuit of goals. Extraversion is associated with positive emotion, sociability, exploratory activity, and reward seeking. Agreeableness is more or less synonymous with

being kind, sympathetic, cooperative, warm, and considerate. Neuroticism can be understood as activity of negative emotion systems such as fear, sadness, anxiety, and guilt.

Genetic variance accounts for about 57% of variance in adult population's *openness,* 49% for *conscientiousness*, 54% for *extraversion*, 42% for *agreeableness*, and 48% for *neuroticism* (Bouchard, 2004). Likewise, the Big Three are heritable: Genetic variance accounts for about 50% of variance in adult population's *positive emotionality*, 44% for *negative emotionality*, 52% for *constraint.*

Evidence to support those findings and for the average effect size of genetic variance in predicting personality attributes was furnished by a recent meta-analysis. (A meta-analysis is a statistical combination and summary of many studies that have researched the same subject in one analysis, which provides stronger evidence than the results of any single study.) That meta-analysis included 62 independent effect sizes, more than 100,000 participants, men and women and of all ages, and it found the average effect size of genetics to be .40, meaning that 40% of individual differences in personality are due to genetic influences, while 60% are due to environmental influences (Vukasović & Bratko, 2015).

Heritability of personality traits appears to be stable over time, or as people age (Loehlin & Martin, 2001). Specifically, using the Eysenck personality scale and a twin registry of 5,400 pairs of twins, researchers found that heritabilities were reasonably stable across age for *psychoticism*, *extraversion*, and *neuroticism*. The personality trait *lie*, or social desirability, showed some influence of genetics and shared environment in all but the elderly age group. Personality traits do tend to change over time, with *psychoticism*, *extraversion*, and *neuroticism* decreasing as people get older and *lie* increasing as people get older (Loehlin & Martin, 2001). Within a longitudinal sample of twins, *psychoticism*, *extraversion*, and *lie* stopped or reversed their trends between ages 56 and 62, whereas levels of *neuroticism* continued to drop (Loehlin & Martin, 2001). The pattern and extent of personality change over time are themselves heritable, as evidenced by more similar patterns of personality change in monozygotic relative to dizygotic twins (McGue, Bacon, & Lykken, 1993). Additionally, the heritability of personality traits appears consistent across cultures (Yamagata et al., 2006).

Cognitive ability, closely tied to personality attributes, has a substantial level of genetic influence, reaching a peak .88 heritability estimate in adulthood (Bouchard, 2004). Further, social attitudes are also heritable. For example, conservatism and right-wing authoritarianism each have a heritability estimate of about .55 (Bouchard, 2004). Religiosity seems to be somewhat heritable, with variance in genetics accounting for 30% to 45% of the trait's variance in an adult population (Bouchard, 2004). Even such personality tendencies as nostalgia and self-enhancement are heritable at estimates of .29 and .37, respectively (Luo, Liu, Cai, Wildschut, & Sedikides, 2016).

As for the future of research examining the genetic basis of particular personality traits, burgeoning technology and methodology will lead the way. Data from molecular genetics and brain physiology will likely contribute to understanding the genetic basis of personality traits (Bouchard & Loehlin, 2001). So far, a few specific genes have been tied to a few specific traits. For example, the type 4 dopamine receptor (DRD4) gene is associated with novelty seeking, or the desire to pursue new experiences (Cloninger, Adolfsson, & Svrakic, 1996; Ekelund, Lichtermann, Järvelin, & Peltonen, 1998). The theory is that people with one form of this gene are deficient in dopamine and therefore seek out thrills to increase

dopamine release. Another gene, the serotonin transporter gene 5-HTTLPR, which regulates serotonin, is associated with neuroticism (Jang et al., 2001; Munafò et al., 2009). Although these effects are small, they do provide insight into the genetic bases of particular traits.

In summary, heritability is the proportion of phenotypic variance in a trait attributable to genetic variance in that population. A wide body of evidence supports that personality traits are heritable. Although most research in this domain has been conducted using the Big Five personality scale, personality traits as defined by different models seem to be heritable. Specifically, they tend to be heritable in the 40–50% range. Behavioral genetics research – twin, adoption, and family studies – furnishes the empirical evidence to decipher the relative contributions of genes and environment to personality traits. There is evidence that personality change across age is heritable and that the heritability of traits is consistent across different cultures. Modern technological and methodological advances may allow future research to further delineate which genes predict which personality traits.

HEXACO Model of Personality

Kibeom Lee[1] and Michael C. Ashton[2]

[1] *University of Calgary*
[2] *Brock University*

The HEXACO model of personality structure consists of six basic dimensions: Honesty-Humility (H), Emotionality (E), Extraversion (X), Agreeableness (A), Conscientiousness (C), and Openness to Experience (O). According to the HEXACO model, these six dimensions can be used to summarize people's personalities and to classify personality traits.

Origins

The HEXACO framework originated in lexical studies of personality structure. In these investigations, researchers identify the familiar personality-descriptive terms (typically adjectives) of a given language, and obtain self- (or observer) ratings on these adjectives from a large sample of persons. These ratings are then analyzed to identify the broad dimensions that underlie these personality traits. By finding the largest set of dimensions that is recovered widely across lexical studies conducted in various languages, researchers can determine the major factors of personality variation.

Early lexically-based research in the English language produced the five personality dimensions that were the basis for the Big Five or Five Factor Model of personality structure. However, this early research was based only on one language and was limited by the small variable sets that could be analyzed with the limited computing power available. When larger variable sets were examined in English and in various European and Asian languages, it became clear that six (but no more than six) personality factors could be widely recovered (Ashton, Lee, Perugini et al., 2004).

Listed below are some terms that typically define the two poles of each of the six lexical personality factors:

Honesty-Humility (H): fair, honest, loyal, sincere, unassuming versus boastful, deceitful, greedy, hypocritical, pompous, pretentious, sly

Emotionality (E): anxious, emotional, fearful, oversensitive, sentimental, vulnerable versus brave, independent, self-assured, stable, tough

Extraversion (X): active, cheerful, extraverted, lively, outgoing, sociable, talkative versus introverted, passive, quiet, reserved, shy, withdrawn

Agreeableness (A): agreeable, gentle, lenient, mild, patient, peaceful, tolerant versus choleric, ill-tempered, quarrelsome, stubborn

Conscientiousness (C): careful, diligent, disciplined, organized, precise, thorough versus absent-minded, irresponsible, lazy, negligent, reckless, sloppy

Openness to Experience (O): creative, innovative, intellectual, ironic, unconventional versus conventional, shallow, unimaginative

In most lexical studies of personality structure, the Openness factor has been interpreted variously as Intellect, as Imagination, or as Unconventionality, depending on the terms that define the factor most strongly. Differences across investigations in the content of this factor are partly due to differing approaches used in selecting the variable sets. In some lexical studies of personality structure, researchers have included terms describing mental ability but have excluded terms describing conventionality or unconventionality; in other studies, the opposite rule has been followed. The HEXACO model follows the common tendency to consider mental ability as a domain of psychological variation separate from that of personality characteristics.

One noteworthy result of the various lexical studies of personality structure was that terms describing altruistic tendencies – such as generous, kind, and soft-hearted – would show their primary loadings sometimes on Honesty-Humility and sometimes on Agreeableness (and occasionally even on Emotionality). In some studies, altruism terms would chiefly define a broad Honesty-Humility factor, leaving a narrower Agreeableness factor, whereas in other studies, altruism terms would chiefly define a broad Agreeableness factor, leaving a narrower Honesty-Humility factor. The superficial differences between solutions of these two kinds tended to obscure their similarity, but as explained in a later section of this report, the tendency for altruism terms to divide their loadings across Honesty-Humility and Agreeableness (and also Emotionality) is consistent with the theoretical interpretation of those factors.

Some research studies have been conducted to examine the similarity of the six-factor solutions obtained from various languages' personality lexicons to the hypothesized six-factor structure. In some investigations, marker scales representing the HEXACO factors have been administered along with adjectives representing the obtained six lexical factors of a given language. These studies have generally showed fairly strong convergent and much weaker discriminant correlations between the two sets of scales (see summary in Ashton & Lee, 2010). In another investigation, layperson judges rated the conceptual similarity of HEXACO factor definitions to sets of adjectives representing the six lexical factors of various languages. That study showed generally high convergent similarity ratings and much lower discriminant similarity ratings (see summary in Ashton & Lee, 2010).

Assessment

The instrument most widely used in assessing people's levels of the HEXACO factors is the HEXACO Personality Inventory – Revised (HEXACO-PI-R). This personality inventory can be administered in self-report or observer report form; the full-length version

contains 200 items, but the 100-item and the 60-item versions are more widely used in personality research. Scale scores are reported for each of the six broad HEXACO factors and for four narrower traits (often called facets) within each of the factors; a 25th facet-level scale, Altruism, is intended to load on three factors and is not a constituent of any single factor scale (Ashton & Lee, 2009).

The facet-level scales of each factor are as follows (facet names in parentheses): Honesty-Humility (Sincerity, Fairness, Greed Avoidance, Modesty); Emotionality (Fearfulness, Anxiety, Dependence, Sentimentality); Extraversion (Social Self-Esteem, Social Boldness, Sociability, Liveliness); Agreeableness (Forgivingness, Gentleness, Flexibility, Patience); Conscientiousness (Organization, Diligence, Perfectionism, Prudence); Openness to Experience (Aesthetic Appreciation, Inquisitiveness, Creativity, Unconventionality).

The HEXACO-PI-R was developed broadly on the basis of Douglas Jackson's principles of test construction, and consequently has shown relatively little influence of self-report response biases, such as social desirability. Scale intercorrelations have been relatively low and self/observer agreement has been relatively high (e.g. Lee & Ashton, 2013).

Comparisons with Five-Factor Model

The HEXACO factors can be compared with those of the well-known "Five Factor Model (FFM)", which became the predominant personality structural model during the 1980s. Whether judged in terms of content or in terms of empirical associations, the HEXACO Extraversion, Conscientiousness, and Openness factors are very similar to their counterparts in the FFM. HEXACO Agreeableness and Emotionality roughly represent blends of Agreeableness and Neuroticism in the FFM, such that the ill-temper associated with FFM Neuroticism defines the low pole of HEXACO Agreeableness, and such that the sentimentality associated with FFM Agreeableness defines the high pole of Emotionality. HEXACO Honesty-Humility has some overlap with FFM Agreeableness; however, Honesty-Humility, Emotionality, and Agreeableness also contain considerable variance not captured within the five-dimensional models (Ashton & Lee, 2019).

Theoretical Basis

The content of the HEXACO factors led to suggestions regarding the adaptive trade-offs associated with higher and lower levels of each dimension. According to these suggestions, three of the HEXACO factors involve higher or lower levels of different forms of altruism or prosocial tendency, and the other three HEXACO factors involve different forms of endeavor or engagement (Ashton & Lee, 2007). The proposed benefits of having higher and lower levels of each dimension are as follows:

Honesty-Humility: gains from cooperation with others vs. gains from exploiting others
Agreeableness: gains from cooperation with others vs. avoiding losses from being exploited by others
Emotionality: reduced harm to self and kin vs. potential gains from exposing self and kin to harm

Extraversion: gains from social endeavor (mates, friends, allies) vs. avoiding costs of social endeavor (energy, risks from social environment)

Conscientiousness: gains from task-related endeavor (material gains, safety) vs. avoiding costs of task-related endeavor (energy)

Openness to Experience: gains from idea-related endeavor (material and social gains from discovery) vs. avoiding costs of idea-related endeavor (energy, risks from natural and social environment)

The HEXACO Model in Research

Although the HEXACO model of personality has been used in a variety of psychological research, many investigations using the HEXACO model have focused on the Honesty-Humility factor. Several categories of such investigations are summarized in the following subsections.

Ethical and Unethical Behaviors in the Workplace

The HEXACO model has been shown to be particularly useful in predicting some moral and honest (versus unethical and delinquent) behaviors in various contexts. In particular, self- and observer reports of the Honesty-Humility and Conscientiousness factors have figured prominently in predicting workplace behaviors such as organizational citizenship, counterproductivity, unethical decision-making, dishonest negotiation tactics, manipulative influence tactics, and others (e.g. Cohen, Panter, Turan, Morse, & Kim, 2014; see also meta-analysis by Pletzer, Bentvelzen, Oostrom, & De Vries, 2019). The same two factors are also associated with guilt proneness (Cohen, Wolf, Panter, & Insko, 2011).

Direct Observations of Cheating

The HEXACO model has been used in studies involving behavioral measures of dishonest behaviors. In these studies, participants are placed in situations in which they may feel tempted to cheat for some gain (e.g. misreporting the outcome of coin tossing to get a monetary award). In various experiments, people lower in Honesty-Humility – as assessed through self-reports provided anonymously – have been more likely to engage in such behaviors. The HEXACO model generally outperforms the Five-Factor Model in predicting objective cheating behaviors primarily because of the Honesty-Humility factor (Hilbig & Zettler, 2015).

Selfish Actions in Economic Games

Low Honesty-Humility has been shown to be associated with selfish actions in economic games. For example, persons lower in Honesty-Humility are more likely to engage in unilateral defection against cooperating players in the Prisoners' Dilemma Game (Zettler, Hilbig, & Heydasch, 2013), and also to engage in "free riding" behaviors in the Public Goods Game (Hilbig, Zettler, & Heydasch, 2012). In the Dictator Game,

people lower in Honesty-Humility tend to allocate more money to themselves, whereas people higher in Honesty-Humility tend to allocate the money equally. In the Ultimatum game, by contrast, people lower in Agreeableness tend to reject unfair offers made by the other player, whereas people higher in Agreeableness tend to accept those offers (Hilbig, Zettler, Leist, & Heydasch, 2013; see also Thielmann, Spadaro, Balliet, in 2020 for a meta-analysis).

Ethical Leadership

Various leadership styles have been investigated in relation to personality traits. Honesty-Humility and Conscientiousness have been found to be the two main personality factors underlying the ethical leadership style, whereby the leader promotes followers' moral behaviors by being a model of such behaviors. Other HEXACO factors are also related to other leadership styles, such as charismatic, supportive, and task-oriented leadership (De Vries, 2012).

Approach to Sex, Money, and Power

Honesty-Humility is strongly implicated in people's approaches to sex, money, and power. People lower in Honesty-Humility are more likely to pursue a short-term mating strategy, to view romantic relationships as a game, and to engage in quid pro quo sexual harassment. Lower Honesty-Humility has also been found to predict conspicuous consumption (e.g. ostentatious displays of wealth) and materialism (e.g. defining one's success in term of material wealth). Finally, persons lower in Honesty-Humility have a stronger motivation to obtain power over many other people and to reach the top of the social hierarchy (Lee, Ashton, Wiltshire, Bourdage, Visser, & Gallucci, 2013).

Risk-taking Behaviors

The personality correlates of risk-taking behaviors tend to differ depending on the risk-taking context. In general, physical risk-taking behaviors are negatively correlated with Emotionality and Conscientiousness (and Openness to Experience, if the risk-taking behavior is motivated by a desire to pursue novel experiences). Honesty-Humility, in contrast, predicts financial risk-taking such as high-stakes gambling and short-term speculation. In general, people lower in Honesty-Humility (and people lower in Emotionality) are more willing to take physical and/or financial risks for pursuit of wealth or of social status and power (Ashton, Lee, Pozzebon, Visser, & Worth, 2010; Weller & Tikir, 2011).

Personal Values

Empirical research on personal or social values has identified two main underlying dimensions. One dimension is called Self-Transcendence (versus Self-Enhancement), which is characterized by values of benevolence and universalism. The other dimension is called Openness to Change (versus Conservation) and is characterized by values of independence and autonomy. The two value dimensions have been found to correspond

roughly to the Honesty-Humility and Openness to Experience factors, respectively. Honesty-Humility and Openness to Experience have also shown significant links with two political ideology variables that correspond fairly closely to the two value dimensions, namely Social Dominance Orientation (SDO, a preference for inequalities between groups) and Right-Wing Authoritarianism (RWA, a willingness to submit to established authority and tradition), respectively (Lee, Ashton, Ogunfowora, Bourdage, & Shin, 2010).

Assumed Similarity/Similarity Among Social Partners

The associations of Honesty-Humility and Openness to Experience with the two basic value dimensions suggest that these two personality factors might play important roles in the formation of social relationships. Given the importance of personal values to people's identity, people may prefer to associate with persons whose values are similar to their own. Consistent with this reasoning, close friends and romantic partners tend to be somewhat similar to each other in Honesty-Humility and Openness to Experience, but not in the other HEXACO dimensions. Furthermore, levels of assumed similarity (i.e. the extent to which one perceives one's friend or partner to be similar to oneself) for Honesty-Humility and Openness to Experience are even higher than the actual levels of similarity. These findings suggest that people are likely to form or maintain social relationships with those who are similar in these two personality factors, presumably due to their links with personal values (Lee, Ashton, Pozzebon, Visser, Bourdage, & Ogunfowora, 2009).

Relations to the "Dark Triad"

Three socially aversive personality traits conceptualized in social and clinical psychology have been frequently examined together since the early 2000s. These personality traits – Machiavellianism, Narcissism, and Psychopathy – have been collectively named the Dark Triad. Several studies have shown that the HEXACO model can account for the variance in the Dark Triad fairly well. Specifically, the common variance shared by the three personality traits is essentially equivalent to low Honesty-Humility (Hodson, Book, Visser, Volk, Ashton, & Lee, 2018). In addition, some of the unique characteristics of each of the Dark Triad are also accounted for by the other HEXACO factors. For example, Psychopathy is significantly linked to (low) Emotionality and (low) Conscientiousness, whereas Narcissism is significantly linked to Extraversion (Lee et al., 2013).

Independent/Interdependent Self

Nathan N. Cheek[1] and Jonathan M. Cheek[2]

[1] *Princeton University*
[2] *Wellesley College*

The *self* represents individuals' understandings of who they are. More than 100 years ago, William James (1890) argued that a complete understanding of the self required that psychologists recognize the multidimensional nature of the self-concept. James' approach proved fundamental in shaping modern psychology's study of the self – indeed, the conceptualization of the self as defined by multiple, relatively independent constituents is the dominant approach in contemporary self and identity research.

Between James and the present approach to the self, however, psychology did not always study the self as multidimensional. Much of the work on the self in the mid-1900s focused on individual, private, and unique aspects of identity, with researchers from the United States, Canada, and Western Europe theorizing about the self as a largely separate entity, unconnected to other people. Over time, this focus expanded with the development of new theoretical approaches emphasizing the distinction between individuals' private self-views and the public self they present to others, the role of self-categorization and group membership in self-definition across cultures, and the importance of close relationships to people's understanding of who they are. Drawing on these theoretical developments, along with the burgeoning literature on cross-cultural differences in how people understand the self and others, Markus and Kitayama (1991) proposed the broad distinction between an *independent self-construal* that defines and understands the self without connection to others, and an *interdependent self-construal* that defines and understands the self in relation to other individuals and groups. People with an independent construal of the self view the self as unique, private, and autonomous, whereas people with an interdependent construal of the self view the self as related to others, incorporating and referencing the views of other people and groups in their identity. This perspective has become the most prominent approach to understanding the structure of the self, and substantial research has explored the influence of independent and interdependent understandings of the self on cognition and emotions. The rest of this entry provides an overview of the measurement of how individuals understand and value different aspects of identity; how culture shapes different

understandings of the self; some connections between cognition, emotions, and the self; and future directions in research on self and identity.

Measurement and Conceptualization

The most common method for assessing the degree to which participants define themselves independently or interdependently is with Likert-type scales. The Self-Construal Scales constructed by Singelis (1994) are by far the most widely used measure, and they assess the degree to which participants construe the self independently and interdependently. The Self-Construal Scales follow the independent-interdependent distinction and therefore consider interdependent aspects of identity broadly. However, substantial research has shown that there are at least three components of the interdependent self: the relational self, which includes romantic and platonic relationships with close others; the public self, which includes one's reputation and public image in the eyes of others; and the collective self, which includes one's group memberships and connections to larger collectives (see Table 1) There are also scales to measure the extent to which people value or define the self through these more specific components of the interdependent self. For instance, Cross, Bacon, and Morris (2000) developed the Relational-Interdependent Self Construal Scale to measure the extent to which people define the self through relationships. The Aspects of Identity Questionnaire (Cheek & Cheek, 2018) measures the importance people place on the independent self as well as each of the three components of the interdependent self, thereby measuring individuals' orientation toward each of the four selves.

When researchers want to make causal claims about the influence of different identities, one common strategy is to attempt to activate or prime a specific self-construal. Classic research in the 1980s, for example, used mirrors and video cameras to make participants attend to the public self (i.e. the self as seen by others), and other techniques involve having participants consciously think about how they are different from or connected to others (e.g. their family) or circle individual or collective pronouns (e.g. "I" and "me" versus "we" and "us") in stories (Brewer & Gardner, 1996). These methods are thought to make particular identities and self-construals temporarily more salient, which can then allow researchers to test their causal influences on variables of interest. Additional measures and manipulations of the independent and interdependent self are reviewed by Cross, Hardin, & Gercek-Swing (2011).

Table 1 Independent and Interdependent Aspects of the Self

Aspect of identity	Features	Example
Independent self	Individual traits, values, and abilities	"I am an introspective person."
Interdependent self		
Relational self	Close relationships with others	"I am Joe's partner."
Public self	Social roles, reputation, and public image	"I am popular."
Collective self	Memberships in groups and social categories	"I am Southern."

Culture

Markus and Kitayama (1991) proposed the distinction between independent and interdependent selves based on a review of the literature on cross-cultural differences in the self. Western, individualistic cultural contexts afford more independent self-construals, and in this view an autonomous self that pursues personal needs and goals and resists conformity is seen as mature. In contrast, collectivist cultural contexts afford more interdependent self-construals, and in this view a mature self is one that considers the needs of close others and the group, maintaining harmonious social ties rather than pursuing individual self-interest without regard to norms and the needs of others. Interdependent self-construals are conceptualized as more prominent in East Asian and other non-Western societies and as less prominent in Western societies. Recent work has also shown that independent selves are more common in middle- and upper-class Western cultural contexts, whereas Western working-class contexts afford more interdependent selves, though the latter are a result of the need to rely on and engage with others as a result of low socio-economic status rather than a broader, institutionally-perpetuated cultural emphasis on relatedness as in East Asian cultural contexts (for discussion, see Stephens, Markus, & Phillips, 2014). Importantly, individuals can have both independent and interdependent views of the self. Thus, these views are defined as relatively orthogonal, but social and cultural contexts tend to make one or the other more prominent.

Cognition

Substantial research indicates that how individuals understand the self influences their social and nonsocial cognition. In particular, people with more interdependent views of the self attend more to the thoughts and opinions of others, pay more attention to conversational norms, and are more likely to consider social norms when making decisions than people with more independent views of the self (e.g. Haberstroh et al., 2002). Similarly, when thinking about the behavior of others, people for whom interdependent aspects of the self are more important are more likely to make situational rather than dispositional attributions for behavior. Interestingly, understandings of the self influence relatively non-social cognition as well: valuing interdependent relative to independent aspects of the identity predicts attending to contextual features more than specific elements within a visual scene or system (e.g. Lewis, Goto, & Kong, 2008).

Emotion

Understandings of identity may also influence individuals' emotional experiences. Kitayama, Karasawa, and Mesquita (2004) argued that independent views of the self are associated with more socially disengaging emotions (e.g. anger), whereas interdependent views of the self are associated with more socially engaging emotions (e.g. shame). That is, some emotions involve and arise from social relations and interdependence, whereas others arise more from independence and experiences and feelings of the self as separate

from others. Broadly, the emotional experiences of individuals who understand the self more interdependently may be shaped by social influence and relational ties more than the emotional experiences of more independent individuals.

Future Directions

Research on the self continues to grow, and although the broad distinction between the independent self and the interdependent self continues to provide a useful theoretical framework, many researchers are now exploring the limits to this general dichotomy. For example, as researchers explore different cultural features, it becomes important to consider more specific components of the interdependent self. The cultural variable tightness-looseness, which describes the cultural strength of norms, is likely to influence the public self more than collective self, whereas the opposite is likely true of the variable individualism-collectivism. Hence, examining only "the interdependent self" provides only a partial picture to the cultural dynamics at play. Moreover, as the psychology of the self extends to more countries beyond North America and East Asia, the range of identities and self-construals will likely expand, requiring reassessment of classic theory based on the independent-interdependent framework. Vignoles et al. (2016), for example, recently proposed a seven-dimensional model that substantially revises the original broad distinction highlighted by Markus and Kitayama 30 years ago, suggesting that there are more ways to be independent and interdependent. Contemporary work continues to build on and refine classic work on the self, and although specific models of the self may change over time, the independent-interdependent distinction will remain valuable at least insofar as it draws attention to the role of others in the self, and the theoretical importance of understanding the self both privately and socially across different societies, time periods, and cultural contexts.

Personal Construct Theory of George A. Kelly

Benjaman To and Keri Ka-Yee Wong

University of Cambridge

Personal Construct Theory (PCT)

Kelly's Personal Construct Theory (1955) offers a theoretical perspective of how people make sense of their worlds and proposes that through the continuous testing of personal constructs, and refinement, the individual is able to understand the environment around them and be better placed to predict outcomes of future events. This theory challenges the dogma in psychology at the time, where the individual is the subject of their actions (behaviorism) and instead, that "Every man is, in his own particular way, a scientist."

Unlike *accumulative fragmentalism*, the notion that discoveries involve verifying individual "fragments" of information that allow the individual to make sense of the situation when they all fit into place, Kelly's theory of *constructive alternativism* states that any particular event can have several different interpretations that can all be entertained at once, without the need to refute one before considering another. Here, *personal constructs* are binary labels (e.g. happy-sad, friendly-unfriendly) that can aid the interpretation of experiences. What makes constructs personal is that even though individuals may share the same labels, the meaning of the construct is unique to the individual. This, Kelly proposed is what gives rise to individual differences in personality. The purpose of a construct is to influence what the individual thinks will happen and subsequently influence their course of action. Therefore, one's experience of a situation may be dictated by the constructs used to formulate the expectation and not by one's reality.

In addition to personal constructs, there are 11 corollaries:

1) Construction corollary: anticipation is dependent on past experiences.
2) Experience corollary: when an outcome is different from that predicted by the construct, it is reconstrued to change future expectations.
3) Dichotomy corollary: experiences are stored as constructs, and then we can analyze the world through them.

4) Organization corollary: constructs are connected to each other in a network of relationships that may be loose or tight.

5) Range corollary: constructs are only useful in a limited range of situations.

6) Modulation corollary: constructs can only be modulated if they are flexible enough to accommodate new information.

7) Choice corollary: we choose to expand our constructs or stay with our current constructs.

8) Individuality corollary: as everyone's experience is different, their constructs are different.

9) Commonality corollary: many experiences are similar or shared, leading to similarity of constructs.

10) Fragmentation corollary: many of our constructs conflict with each other.

11) Sociality corollary: the extent to which two individuals can interact depends on the extent to which they are using similar construct systems. As a result, when constructs are challenged or incomplete, it can precipitate emotional states, e.g. anxiety, confusion, anger, fear.

Kelly's (1955) PCT has been adapted by Dalton and Dunnett (1992) to incorporate sociality and communality as key principles.

Nature of Personality Adjustment

According to the PCT, successful personality adjustment involves not just the creation of personal constructs but the ability to modify our personal constructs based on our past experiences. Kelly described two ways in which this can occur:

- *The Circumspection-Preemption-Control Cycle* (C-P-C cycle informally known as the "if-then" approach): the "if" refers to the construct and selection of action which is divided into three phases: (1) circumspection: propositional constructs used to generate potential course of actions, (2) pre-emption: after assessing the situation, one action is selected, and (3) control: course of action planned according to the pre-emptive decision. The "then" refers to the evaluation of the outcome and appropriate modification of the construct. If it was a successful outcome, this would strengthen the construct; if it was unsuccessful, an individual will try an alternative (i.e. preemptive stage) or start generating novel actions (i.e. circumspective stage).
- *Creativity cycle* (informally known as the "what-if" approach): constructs are viewed in a much less rigid way allowing the exploration of novel possibilities in a safe theoretical capacity.

According to this theory, unsuccessful personality adjustment involves an inflexible construct that prevails despite repeated invalidation, which is characteristic of someone experiencing a psychological disorder. These features include:

- Impermeable constructs: construct does not change in spite of new evidence becoming available, which limits development of an individual's constructs.
- Ignorance of interpretations: individuals feel problems result from certain "facts" in their life and are ignorant to what is actually happening.

- Restrictive range of convenience: constructs can only predict a limited range of situations, which can manifest as anxiety due to inability to predict events.
- Incomplete constructs: constructs that lack sufficient information or details for the person to deal with the present scenario, which can manifest as confusion or uncertainty.

Personality Assessments Based on PCT

Kelly designed two methods to measure the nature of an individual's constructs and how they develop: (1) the *Repertory Grid*, a variant of the Role Construct Repertory Test and *self-characterization*. For the Repertory Grid, the individual is asked to identify "elements" involving any aspect of the world (e.g. people, objects, events) that is relevant to the individual. The "sequential triadic method" involves grouping elements into threes and the individual has to indicate how two of them are similar by identifying a common construct, and how the third is different. The grid method combines individual constructs to create the individual's construct system; the more comparisons made, the more applicable this is. There are two inherent assumptions regarding the utilization of this method, that (a) identifying an individual's construct system means we can predict their behavior, and (b) an individual's construct map can be modified by psychotherapy. This mathematical representation of construct systems has been extremely popular because it is flexible, wholly patient-driven and overcomes interviewer bias (Anderson, 1990). The repertory grid has also been trialed for use in patients with paranoia (Garcia-Mieres, Ochoa, Salla, Lopez-Carrilero, & Feixas, 2016) and thought disorders (Bannister & Fransella, 1966), and has shown individuals with cognitive conflicts are more likely affected by major depression (Feixas et al., 2014).

A second, more subjective measure of construct systems, is *self-characterization*. The client writes about their behavior and relationships with others in the third person, with the aim of providing the client with a different perspective of their situation. At the time, this was a very novel, pioneering narrative approach to psychology.

Psychotherapy Based on PCT

One area of psychology that PCT exerted influence is in psychotherapy. Typically, the client would present with a complaint and working with the therapist, the client will determine the maladaptive construct system. There are many different techniques operationalized in a safe environment in order to help the client reconstruct and modify resistant maladaptive personal constructs, including: role playing, dream analysis, and controlled elaboration. The focus here will be on role playing, as it is a novel psychotherapy approach that is based on Kelly coaching dramatics early in his academic career.

- *Enactment* (therapy sessions): the client acts out a certain event with the therapist or other individuals in group therapy, which is thought to expose dysfunctional constructs. Role reversal, where the client acts out the role of the other person, may be used to show why people respond to the client in a certain way. Enactment has been shown effective in family therapy (Nichols & Fellenberg, 2000) and to treat victims of abuse (Plakun, 1998).

- *Fixed role therapy* (real world): Building on the self-characterization sketch, a fixed role script is written by the therapist describing a fictional person who displays a more adaptive construct system than the client. The client then practices the script with the therapist to enhance exposure and acceptance of this novel construct. The fixed role involves the client acting out the adaptive constructs written in the script, but in the real world. Clients are asked to observe how this novel construct affects others' responses, and as this "role" is purely fictional, the client is able to view themselves in a non-threatening way. The idea is that a person's view of themselves depends on their outward actions and so by changing this it might be possible to alter their system of internal personal constructs. Both the script and the acting help provide a mirror on the client's behaviors.
- Other methods include dream analysis, where dreams are interpreted as loose constructs and explored in therapy, and controlled elaboration, where the C-P-C cycle is verbally explored to identify a dysfunctional personal construct and the therapy involves discussing what the potential outcomes are, what the alternative explanations may be, and how they can be managed.

Evaluation of Kelly's PCT

A limited evaluative overview of Kelly's PCT includes a few strengths and limitations. Strengths:

- Provides an analytical view of behavior that is not purely behavioral but also offers insight into the influence of the cognitive aspects of personality.
- Repertory test is a unique way of assessing personality and its use extends beyond psychology and into marketing research and management training programs. Its potential application for anorexia nervosa (Starzomska & Smulczyk, 2011) and eating disorders is interesting.
- Kellian-based psychotherapy represents a pioneering therapeutic approach that is reflected in contemporary cognitive-behavioral therapy.

Limitations:

- Over reliance on rationality; the theory does not account for the irrationality that is inherent in human nature but it assumes the aim of actions undertaken is to ultimately predict the world around us, which may not be always true.
- The repertory test aims to create a population-applicable tool that allows assessment of personal constructs; however, as constructs are unique to the individual, whether such a generalized technique is effective is not known. Even if constructs can be categorized, this does not necessarily mean that they can accurately predict an individual's personality or that psychotherapy would be able to modify it.

Conclusion

Kelly's PCT offers a way to conceptualize personality with novel psychotherapy approaches that may be applicable to fields that extend beyond psychology. The true effects of Kellian psychotherapy have not been witnessed as its application as part of mainstream treatment

approaches has been minimal. It would be interesting to see the effects of its use in personality disorders and in disorders where mental depiction of oneself is misaligned with the physical reality.

Maslow's Hierarchy of Needs

Bernardo J. Carducci

Indiana University Southeast

Abraham H. Maslow proposed a viewpoint of the individual that has become known as the third force in psychology, with the psychodynamic emphasis on unconscious processes and behaviorist emphasis on environmental controls on behavior being the two other forces. The emphasis of this third force has been to enhance the dignity of people by studying the internal processes contributing to their self-directed self-enhancement.

The Motivational Nature of Personality

For Maslow, the driving force behind personality was that individuals were constantly being motivated to meet a variety of biological and psychological needs. The meeting of these needs was assumed to operate in a dynamic process rather than in isolation (Maddi, 1996; Reis & Patrick, 1996). The principal objective of these needs is the motivation of the individual to reach a state of self-actualization. For Maslow, the state of self-actualization involves attempts by individuals to reach their full potential by using their talents and abilities to the fullest extent while trying to achieve personal growth, satisfaction, and fulfillment.

Maslow organized human needs in a manner designed to promote the achievement of this state of self-actualization by grouping them into deficiency needs and being needs (Maslow, 1970): Deficiency needs are the lower, more basic needs necessary for the survival of the individual, including hunger, thirst, safety, and social connectedness. The deficiency needs motivate the individual to engage in behavior designed to bring about the satisfaction of these needs. Being needs are the higher needs necessary for the achievement of a state of self-actualization, including those needs reflecting a desire for wisdom, aspirational development, and a sense of aesthetics.

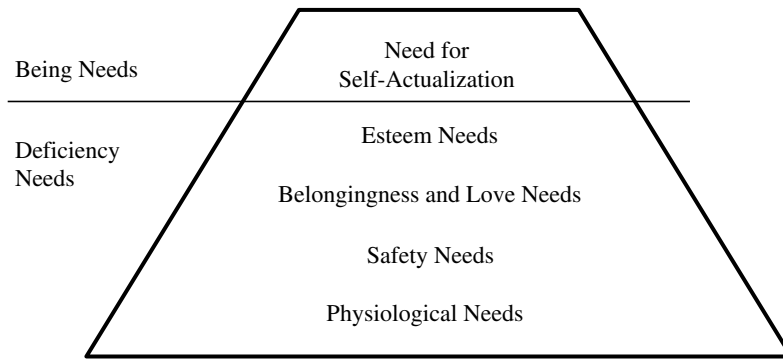
The being needs motivate the individual to engage in behavior designed to bring about their fulfillment (e.g. going to college or an art museum). Deficiency needs are characterized by a lack of something the individual is motivated to supply. Being needs are


Figure 1 Maslow's hierarchy of needs.

characterized by an on-going motivational process of self-enhancement, not a deficiency in a need requiring only satisfaction. The lower needs are considered to be more potent and to have a greater influence on behavior than the higher needs. As a result of these features, the lower needs are also generally satisfied before the higher needs.

The Hierarchy of Needs

Maslow (1970) organized human needs into five basic groups in a hierarchical fashion. The logic of the hierarchy of needs is that the needs at the lower end of the hierarchy exert more power in that they apply a greater sense of urgency to be satisfied than the needs at the next level. Progressing up the hierarchy of needs results in the individual coming closer to achieving the state of self-actualization

At the bottom of the hierarchy are the most basic physiological needs. Physiological needs are those directly related to the survival of the individual. They include the need for food, water, sleep, and elimination. Such needs are extremely potent and can dominate the life of the individual when unfulfilled. For example, ideals like democracy and justice mean little to people who are on the brink of starvation. Maslow proposed that when physiological needs are routinely met, people can devote more of their energies to meeting the next level of needs – safety needs.

Safety needs are those directly related to creating an environment for living that is free from the threat of danger. They include the need for order, predictability, and structure. For most people, safety needs are met by the dwellings in which they live and by the security and predictability they provide. Just as routine seems to add to our sense of safety, changes in our lives seem to create a threat to such a sense of security. Some of the consequence of such threats based on change, ranging from divorce, death of a loved one, natural disasters, and/or terroristic events, include altering dramatically the sense of safety, security, and predictability of our daily lives (cf. Danieli, Engdahl, & Schlenger, 2004; Foa, Hembree, Riggs, Rauch, & Franklin, 2001) and a tendency to become more vulnerable to many kinds of physical (e.g. high blood pressure) and psychological problems (e.g. depression)

(Rahe, Veach, Tolles, & Murakami, 2000; Scully, Tosi, & Banning, 2000). The consistent satisfaction of safety needs allows individuals to begin considering the next cluster of needs – belongingness and love needs.

Belongingness and love needs are directly concerned with the basic desire to feel accepted by and have meaningful interpersonal relationships with others. They include the need to feel a part of some reference group (e.g. family, neighborhood, religious group, or professional organization) and the ability to both receive and give love based on such group membership (e.g. establish meaningful friendships). Belonging to various social organizations, as well as being a member of a family, gives an individual a sense of acceptance and belongingness and helps to meet this category of needs.

Esteem needs are concerned with the desire to have the respect of others and possess a sense of self-respect. Included in having the respect of others are achieving status and recognition within those significant groups and being perceived as a worthy and able member. Esteem needs can be met by being perceived or elected a leader of a group. Such status reflects the confidence and esteem others have for an individual's abilities. Those who are able to satisfy consistently the esteem needs can direct their motivation at the highest level of the hierarchy of needs – self-actualization.

Self-actualization involves the individual's desire to develop his or her abilities to their fullest potential (cf. Batson & Stocks, 2004). Such development involves obtaining a deeper sense of one's own desires and abilities and maximizing their expression in an attempt to bring them together. Such efforts for self-actualization might include taking additional risks and/or making personal sacrifices (e.g. moving to a new location away from family and friends). It is important to note that meeting the need of self-actualization is an ongoing process, not an absolute state of achievement (Polkinghorne, 2001). In addition, while the self-actualization need is at the highest level of the hierarchy, it is also the least powerful. It is for this reason that Maslow felt that very few people are able to satisfy completely this need. For such a need to be achieved, the individual must be extremely motivated from within himself or herself.

Some Points of Clarification on the Hierarchy of Needs

There are a few common misunderstandings about the processes associated with the fulfillment of the hierarchy of needs. One is that although the needs are arranged hierarchically, this does not mean that a person must completely satisfy one group before moving on to the next level. Instead, the lower needs should be satisfied only to the extent that the individual has some relief from them and can devote more attention to the higher needs. The more relief a person has from lower needs, the more attention that person can give to the higher needs. In a related manner, because it is possible to experience more than one need at a time, it is also possible to satisfy more than one need at a time. Finally, even though the lower needs are more powerful, they can be superseded by the higher needs. For example, an individual might sacrifice sleep to work toward an important personal achievement. As such, the expression of the hierarchy of needs is not as cut-and-dried as many people might assume.

Evaluation of the Hierarchy of Needs

Maslow's views have been applied to a wide variety of areas, including psychotherapy (Boorstein, 2000), religion and spirituality (Elkins, 2001; Maslow, 1976), athletic performance (Privette, 2001) and consumer behavior and marketing (Hawkins, Mothersbaugh, & Best, 2007). Although these applications of Maslow's viewpoint provide some support for its utility, criticisms of this perspective include the use of many concepts and processes to describe the operation and expression of personality that are difficult to explain (e.g. Upon what basis did Maslow select the five need categories?) and test objectively (e.g. What is the measure to assess the extent to which an individual is making progress toward self-actualization if it is different for each individual?).

Meaning in Life

Lucas A. Keefer and Aaron Bermond

University of Southern Mississippi

While philosophers and theologians may debate the ultimate meaning of human existence, psychologists focus on the more immediate issue of whether individuals feel that their lives are meaningful. This construct includes a cluster of related epistemic states, including having a general sense that the world makes sense, understanding the purpose of one's actions, and having a sense that one has some significant role to play in the order of things (Martela & Steger, 2016). Below we review key areas of research on the causes and consequences of experiencing a sense of meaning in life.

Humanistic-Existential Perspectives on Meaning

Contemporary philosophers began to carefully attend to the role of experiencing a meaningful existence. Yet despite an interest in the study of human lives, attention to meaning was slow to develop in psychology. It was not until the rise of early humanistic and existential psychology that the field began to attend to the fundamental role of meaning in a healthy and happy life.

Rogers' person-centered approach to psychology made an initial claim to the importance of meaning. By adopting a phenomenological approach that privileges the client's experiences, Rogers proposed that any therapy must begin by understanding the meanings, values, and emotions of the client themselves. Rather than attempting to impose models, stages, or drives from a general theory, this approach works within the person's own views of who they are and their place in the world.

Another influential statement of the importance of personal meaning comes from Frankl's *Man's Search for Meaning*. This landmark work presented the novel thesis that a fundamental human motive is the pursuit of meaning, a massive departure from the prevailing approaches of the day. In support of this claim, Frankl chronicles his experience as a Holocaust survivor and notes the fundamental role of meaning as a resource for coping. From this, he proposes a novel existential therapy designed ultimately to help individuals

find or create meaning to cope with their own challenges (an approach that is broadly effective; Vos, Craig, & Cooper, 2015).

The idea that people are motivated to seek meaning was later echoed in the work of Maslow, although he argues that this motive is superseded by more pressing protective motives for security and survival. Specifically, meaning is part of the pursuit of growth or self-actualization and therefore not an issue for individuals faced with more pressing challenges.

Meaning Maintenance

Are individuals fundamentally motivated to secure meaning in the way that the earlier psychologists propose? According to the Meaning Maintenance Model (Heine, Proulx, & Vohs, 2006), individuals are so motivated to maintain an ordered and coherent understanding of their place in the world that they are both distressed by an experienced lack of meaning (or meaning violation) and motivated to alleviate that distress by restoring a perception of order and predictability.

Research on this model identifies five key meaning-making processes that allow people to restore a sense of coherence (Proulx & Inzlicht, 2012). *Assimilation* and *accommodation* allow individuals to make sense of the environment by either assimilating new data to a known concept or accommodating new information by changing one's schemas. For example, a novel work of art could be understood by assimilation into past categories based on genre or composition. Alternatively, if that work does not cleanly fit a prior label, one could generate a new concept or revise one's understanding of a style to include that work.

Another strategy people enact is *affirmation*: In response to meaninglessness, people can espouse a prior structure that provides them with a sense of structure. This can take many forms, such as affirming religious belief in response to the threat of meaninglessness to restore a sense that the world is structured.

Rather than attempting to affirm a prior meaning framework, another response is to simply identify or construct meaning in the moment. *Abstraction* refers to the process by which individuals faced with chaotic complexity derive a sense of meaningful order by discerning structure. For example, in one study (Proulx & Heine, 2008) participants experienced a threat to meaning either directly (a challenge to their values) or indirectly (by reading a short story by Franz Kafka). In both cases, those who experienced threatened meaning were more effective at detecting patterns in seemingly random strings of letters. The final strategy, *assembly*, refers to a slightly different process: While *abstraction* refers to the process of detecting an existing pattern, *assembly* refers to the process of generating coherent concepts or perspectives to make sense of the world. This kind of creative process in meaning-making is believed to play a crucial role in the efficacy of several forms of therapy.

Meaning and Well-Being

Given that accounts of meaning focus on its basic value, it is perhaps unsurprising that research tends to identify meaning as an indicator of psychological well-being. For example, those who report greater meaning on the Meaning in Life Questionnaire tend to feel

more socially connected, experience more control over their lives, show greater well-being across a range of measures, and report fewer experiences of distress or alienation (Steger et al., 2008).

The Meaning in Life Questionnaire also assesses the extent to which participants are actively searching for or seeking some greater meaning in their lives. Those who report a greater search for meaning in their lives tend to feel less socially connected and be less happy with themselves (Steger et al., 2008). Supporting research also shows that those individuals who showed greater daily fluctuation in their experience of meaning tended to experience lower life satisfaction, more negative mood, and less positive social relationships (Steger & Kashdan, 2013).

In addition to general personality assessments, clinical psychologists have attended to more proximal experiences of meaning. Park (2010) describes this important distinction between a *global* sense of coherence and purpose and a more *specific* sense that a given outcome is comprehensible and meaningful. These two forms of meaning are intimately related: A general sense of meaning can provide a framework for understanding specific stressful events (Park & Folkman, 1997). At the same time, being able to make meaningful sense out of specific events and moments can help to affirm a global sense of meaning.

Research focused on meaning-making finds overwhelming support for the positive coping benefits provided by the ability to understand and ultimately integrate into one's life specific traumatic experiences (for review see Park, 2010). For example, individuals who had lost a limb due to amputation showed greater personal growth and lower risk of depression when they could accept and understand their new circumstances.

Is Meaning Just a Feeling?

While the pursuit of meaning may seem to be the project of hours of armchair contemplation, recent work in social psychology fundamentally calls this into question. King suggests that meaning in life is the result of two independent processes (King, Heintzelman, & Ward, 2016). Meaning can arise from careful deliberate thinking, but a more common source of meaning is *intuitive*; the result of a rapid process that detects coherence in a situation through positive affective cues. Participants reported a greater feeling of meaning in response to felt positive affect and related studies find that inducing temporary negative states like loneliness also decreases perceptions of the global meaning of one's existence.

These findings further suggest that way in which one feels about a situation has a direct effect on the meaning one finds in the moment. In one series of studies, King and colleagues found that incidental positive affect caused people to perceive evidence of paranormal phenomena (e.g. UFO abductions or ghost sightings) to be more meaningful (King et al., 2007). Later work shows that individuals reporting more positive affect also reported greater meaning in life, particularly among those who attribute more significance to events that are, in fact, meaningless (e.g. a traffic light turning red just because the individual was in a rush; King & Hicks, 2009). In another study, participants in the positive affect condition were awarded $20 for completing a task prior to completing a measure that assessed whether or not they could detect coherence in a series of word triads (the words *beach*, *base*, and *basket* are a triad that are coherent triad with the theme *ball*, whereas *nail, orange,* and, *restaurant* are not). When primed with positive mood, participants were more

accurate at intuiting meaningful patterns on this task (Hicks et al., 2010). Research overall suggests an intimate connection between positive mood and the perception of meaning.

In response to this view, there have been several criticisms of the idea that evaluations of meaning can be reduced to positive affect. For example, many psychologists consider a crucial distinction between hedonia, the achievement of positive feeling or pleasure, and eudaimonia, a more enduring state of well-being and happiness long central to Aristotlean ethical philosophy. In support of this distinction, empirical research finds that affective indices of well-being correlate with, but are distinct from, more cognitive aspects like a feeling of autonomy, satisfaction with one's relationships, and a sense of meaning in life (Linley et al., 2009).

Conclusion

Philosophical interest in meaning ultimately led psychologists to study this phenomenon. Practitioners first employed meaning as a therapeutic framework; an essential element in a healthy comportment to the world. Social and personality psychologists, in contrast, have focused on cognitive and situational factors that give rise to the experience of meaning. These projects converge on the central finding that meaning is ultimately an important indicator of well-being, although controversy remains about its unique role.

Neuroticism

Fang Zhang

Assumption College

Neuroticism is one of the higher-order personality dimensions in psychology. Individuals who score high on measures of neuroticism are more likely to experience negative emotions, such as anxiety, sadness, worry, fear, anger, guilt, and loneliness, and are more susceptible to mood shifts. They also are prone to negative thoughts and show a pessimistic attribution style in explaining life events. In addition, they tend to cope with stress poorly and have trouble controlling impulses and delaying gratification. In contrast, individuals with low levels of neuroticism usually are calm, relaxed, even-tempered, and emotionally stable. They are less reactive to stress and tend to report low levels of negative emotion.

Hallmarks of Neuroticism

One of the hallmarks of neuroticism is over-reactivity on the negative emotions. Individuals high in neuroticism tend to be vigilant to possible negative social feedback and are more likely to interpret the normal stresses and ordinary events of everyday life as threatening. They experience negative emotions more easily and strongly after emotionally arousing events and tend to remain negative for longer periods of time compared to others. Emotional instability is another hallmark of neuroticism. Individuals high in neuroticism show more variability in moods over time. In addition to variability in negative affect, high levels of neuroticism also are correlated with greater variability in positive affect. Interpersonally, individuals high in neuroticism report more ups and downs in social relationships as well and score lower on relationship satisfaction than others.

Theories of Neuroticism

Neuroticism has been discussed in major personality theories and is recognized as one of the core dimensions of personality. Nevertheless, conceptualizations of neuroticism differ somewhat across theoretical frameworks.

The Big Five model of personality is based on the lexical tradition in personality research, which analyzes the natural language of personality descriptions by using statistical techniques such as factor analysis. In this model, neuroticism is described as one of the five broad dimensions of normal personality, along with extraversion, conscientiousness, agreeableness, and openness. Robert McCrae and Paul Costa (1992) suggested that neuroticism subsumes six distinct, more specific traits, including anxiety, angry hostility, depression, self-consciousness, impulsiveness, and vulnerability.

In his hierarchical model of personality, Hans Eysenck discussed Neuroticism-Emotional Stability as one of three super traits, the others being Extraversion-Introversion and Psychoticism (Eysenck & Eysenck, 1975). Eysenck believed that these three traits were highly heritable and that each has identifiable physiological substrates. He further proposed that neuroticism consists of a cluster of narrower traits, including anxiety, irrationality, depression, guilt, low self-esteem, tension, shyness, moodiness, and emotionality, each of which, in turn, subsumes a variety of habitual acts.

Neuroticism also has been discussed in the context of Jeffrey Gray's biological theory of personality (Gray, 1990). Gray proposed two underlying brain systems of personality. One is the behavioral activation system (BAS), which is responsive to reward and regulates approach behavior, and the other is the behavioral inhibition system (BIS), which is responsive to punishment and threats and regulates avoidance behavior. Neuroticism has been found to be strongly and positively correlated with the BIS score, and negatively correlated with the BAS score.

Neuroticism also is linked to the dimension of Negative Emotionality in Auke Tellegen's three-factor model of personality. Tellegen (1985) proposed three higher-order personality dimensions – positive emotionality, negative emotionality, and constraint. Negative emotionality is described as reflecting a disposition to experience negative emotions and be involved in adversarial relationships. High neuroticism is found to be linked to negative emotionality.

Measures of Neuroticism

Neuroticism typically is measured using self-report, although observer data obtained from knowledgeable informants, such as spouses, romantic partners, close friends, parents, or professional assessors, also can be used. Self-report measures of neuroticism usually take one of two forms. One form is self-ratings of single-word trait adjectives (for example, relaxed, moody, anxious). The 100-marker measure developed by Goldberg (1992) is representative of such Big Five measures. Respondents rate themselves on 100 trait adjectives on this measure. Shorter lists have been developed in recent years to measure the Big Five, for example, the 40-word *Balanced International English Big-Five Mini-Markers* uses 40 trait adjectives (Thompson, 2008). The other form is the sentence-length item format. In

this format, respondents rate themselves on statements such as "I have frequent mood swings" and "I am not a worrier." Two commonly used measures in this format are the *Revised NEO-Personality Inventory* (NEO-PI-3, McCrae, Costa, & Martin, 2005) and the *Eysenck Personality Questionnaire-Revised* (EPQ-R; Eysenck & Eysenck, 1975). The NEO-PI-3 consists of 240 items, 48 of which measure neuroticism. The EPQ-R has 100 items, with 24 of these measuring neuroticism. Both NEO-PI-3 and EPQ-R are reported to have good reliability and validity.

Life Span Development and Sex Differences

Life span development of neuroticism, like other major personality dimensions, is characterized by both continuity and change (Caspi, Roberts, & Shiner, 2005). Continuity is reflected in the rank-order stability of neuroticism, the degree to which people maintain their rankings over time on levels of neuroticism relative to their peers. A highly anxious 20-year-old most likely remains more anxious than his or her peers at age 30, for example. A meta-analysis of 152 longitudinal studies found rank-order stability of neuroticism to be moderate from childhood to young adulthood, and furthermore, the stability estimate increases with age and reaches a plateau between ages 50 and 70 (Roberts & DelVecchio, 2000). It has been suggested that rank-order stability reflects both genetic factors as well as stabilizing developmental and environment processes, such as the formation of a mature identity and the niche-building processes whereby people create or seek out environments correlated with their levels of neuroticism (Caspi et al., 2005).

Despite such rank-order stability, mean levels of neuroticism change over time. Both cross-sectional and longitudinal studies demonstrate that neuroticism steadily decreases with age, with the greatest decrease in early adulthood (Roberts, Walton, & Viechtbauer, 2006). Such change is thought to reflect psychological maturation over time and varying social roles and experiences at different stages of life. In addition to this normative change, individuals' levels of neuroticism also can be altered by unique life experiences. Positive experiences can lead to temporary or long-term decreases in an individual's neuroticism, while negative experiences can result in increases in neuroticism.

Among the Big Five personality dimensions, neuroticism shows the largest sex difference, with women scoring moderately higher than men on the dimension. This sex difference appears to be quite universal and has been found consistently in many cultures and nations.

Psychopathology and Life Outcomes

Neuroticism should not be confused with neurosis as neuroticism reflects a dimension of normal personality. High levels of neuroticism do not necessarily indicate the presence of psychopathology. Nevertheless, neuroticism is considered to be the greatest risk factor for psychopathology among the major personality dimensions (Kotov, Gamez, Schmidt, & Watson, 2010). High levels of neuroticism are associated with a wide range of psychological problems, including substance abuse, mood disorders (i.e. depression, bipolar disorder),

anxiety disorders, eating disorders, schizophrenia, posttraumatic stress disorder, as well as borderline and paranoid personality disorders (Ormel et al., 2013). Higher levels of neuroticism also are linked with poorer dietary habits, less physical activity, and poorer physical health. Combined with other personality dimensions, neuroticism has been linked to many adverse behaviors and life outcomes, including risky sexual behavior, pathological gambling, smoking, alcoholism, low life satisfaction and happiness, poorer educational attainment and professional success, as well as divorce.

Biological Influences

Research found that neuroticism shows a moderate degree of heritability, suggesting that individual differences in neuroticism are partly accounted for by genetic differences. Many researchers also suggest that individual differences in neuroticism are linked to physiological differences (Bouchard & Loehlin, 2001; Caspi et al., 2005; Vukasović & Bratko, 2015). For example, Hans Eysenck linked neuroticism to reactivity of the sympathetic nervous system, the system that regulates the body's fight-or-flight response in the face of danger. Eysenck hypothesized that, compared to others, people who score high on neuroticism have a sympathetic nervous system that reacts more strongly and negatively to environmental stressors. In recent years, neuroscience and molecular genetic research have focused on discovering connections between neuroticism, on the one hand, and specific genes, neurotransmitters, and neural circuits on the other (Canli, 2008). For example, neuroticism has been linked to variation in genes such as 5-HTT, the gene that codes for the serotonin transporter. Neuroticism and traits associated with neuroticism also have been linked to differences in activation in the amygdala and hippocampus regions of the limbic system, as well as in the medial prefrontal cortex.

Narrative Approach

Rachele Benjamin, Audrey E. Aday, and Anna Vozna

University of British Columbia

Introduction

The narrative approach to personality psychology involves understanding how the individual's self-concept can be conceptualized as an overarching life story, or narrative. These life stories determine how we behave, and how we relate to the people around us. Our stories also determine how we understand our previous motivations, navigate our current environment, and establish an overarching sense of unity and consistency in our behavior. Though a narrative approach to personality has only recently found a mainstream audience, many philosophers and early psychologists laid the groundwork for this approach over the last century.

History and Origins of Narrative in Psychology

One influential idea was William James' theory of the relationship between "I" and "me" (1890). According to James, when individuals say "I" they refer to the aspect of the self that thinks and makes decisions, whereas "me" refers to the aspect of the self that appears to move through space and time. This idea influenced scholars to think about storytelling as part of the self-concept, and considerations of the self as the object of one's thoughts and experiences (Hermans et al., 1992). Another strong influence was Lev Vygotsky, whose work on the relationship between language and the development of thought, and the importance of symbolic meaning and other cultural products in shaping the self through language, influenced later work on the how the self and our knowledge of the world is constructed by stories and narratives (Bruner, 1991; Vygotsky, 1964).

In the psychoanalytic tradition, people's stories, even those that emerge in dreams, are believed to be meaningful aspect of the self (Freud, Strachey, & Freud, 1953). However, modern theorists point out that psychoanalysis lay relatively dormant for some time after the early twentieth century, and furthermore, that even in this era scholars did not attempt to think

about humans as storytellers – building and relaying their own life stories (McAdams, 2001). Scholars argue that the first theory to explicitly articulate this notion was Silvan Tomkins' script theory (1978), which posits that individuals are dramatists, organizing their lives according to scenes and plots (McAdams, 2001). In this model, people's behaviors and beliefs are understood to be rule-based, adhering to internalized scripts that guide behavior (Tomkins, 1978). These theorists laid the groundwork for life stories, and how our identities are constructed through narrative.

Narrative Theories of Personality

Life Stories

Today, there are many prominent scholars who take a narrative approach to personality. McAdams (1985) developed an influential theory of life stories, which proposes that an individual's life story is an internalized, evolving structure that helps people organize their experiences such that they have a sense of unity and consistency. The theory suggests that individuals have a life narrative that is complete with scenes, characters, plots, and themes. Having a coherent and internally-consistent life narrative allows individuals to impose meaning upon the present, navigate the future, and reconstruct their pasts (McAdams, 1985).

Three-Level Framework

One question that emerges is how personality can include a narrative construction of the self, but also other aspects of personality that are more familiar to personality research (e.g. traits and motivations). To address this question, McAdams presented a three-level framework (1995, 2001) which posits that personality can be conceptualized as three distinct elements. At the most basic level (Level I) are *dispositional traits*. Such traits are global, unchanging, and relatively stable across situations; they account for an individual's most basic tendencies and consistently predict thoughts, behaviors, and feelings across a wide variety of contexts. Perhaps the best-known exemplars of dispositional traits include those captured by the Big Five (i.e. openness, conscientiousness, extraversion, agreeableness, neuroticism), though other traits such as depressiveness, sensation seeking, or masculinity/femininity are similarly descriptive of Level I. At the next level in personality (Level II) are *characteristic adaptations* (or *personal concerns*). Unlike dispositional traits, characteristic adaptations are dependent upon context; they interact with time, place, and social roles to influence one's response to a given situation. Examples of characteristic adaptations include personal goals and motives, defense mechanisms and coping strategies, mental representations of self and other, values, and beliefs, developmental tasks, and domain-specific skills and interests. Yet as McAdams (1995, 2001) notes, these two descriptive levels of personality may not provide a full description of personality. For most adults, especially those living in societies which place emphasis on the self (e.g. contemporary Western society), identity is primarily constructed through the telling of life stories. Thus, the final level of personality (Level III) is the level of identity as a life story.

Level III encompasses the various ways in which individuals seek to construct their life narrative in a way that provides meaning, unity, and purpose. While one person may convey their life story as a comical narrative, another person may choose to model their life story as a dramatic saga. Such storytelling strategies are necessarily reflective of individual identity and personality. The three-level framework maintains that each of the three levels of personality are not derivative of one another, but rather offer their own unique conceptualization of individual differences. Each level may be examined to gain meaningful insight into personality. Whereas dispositional traits present an initial sketch of personality and characteristic adaptations add some detail, life stories integrate these two levels and create meaning (McAdams, 2001).

Process Model of Self-Development

Another model that attempts to integrate storytelling and narrative with the larger self-concept is McLean, Pasupathi, and Pals' (2007) process model of self-development. They propose that the act of storytelling is essential to the creation and maintenance of the self. Specifically, telling a *situated story*, or an autobiographical description of their thoughts and feelings in a particular situation, is an act of expressing and maintaining one's self-concept, but may impact one's self-concept and life story. This model provides insight into how one's narrative identity develops and is maintained. Over time, the act of telling stories leads to the development of a life narrative, which then influences one's future decision-making and subjective interpretation of events, and is theorized to even affect other aspects of personality such as self-esteem (McLean et al., 2007). In this sense, our stories can shape our identities, and in turn, our identities dictate the particular aspects of the stories we tell in any given situation.

Dialogical Self Theory

One particularly influential idea is the Dialogical Self Theory (DST; Hermans, Kempen, & Van Loon, 1992). According to this theory, one's self-concept is made up of many different versions of oneself; for example, the self includes ideas about the person one might become, and the person one might be afraid of becoming (Hermans et al., 1992). Different versions of the self are capable of being in disagreement with each other, and the self-narrative can be viewed as a collection of each self, occupying different positions in space and time. These "many selves" form a complex, narratively-structured self-concept (Hermans et al., 1992). Under this model, individuals are able to take an outside perspective on their own behaviors and motivations, having many different vantage points depending on the version of themselves that they are currently occupying. It also gives them the opportunity to view themselves as protagonists in their own life narrative (Hermans et al., 1992). The benefit of this approach is that the self can be understood as changing throughout time, and in different circumstances, and yet it can still adhere to an internally-consistent narrative structure. Another benefit is that it is more descriptive of personality outside of a Western cultural context, where having "many selves" and even imaginary characters in disagreement with each other is a common occurrence. On the other hand, self-contained individualism is a uniquely Western way of structuring the self (Hermans et al., 1992).

Narrative Therapy

One way in which taking a narrative approach has benefited the field more generally is through its influence on narrative therapy. Narrative therapy was developed by White and Epston (1990) with the aim of helping individuals reframe their lived experiences to create a more positive self-narrative. The process involves encouraging individuals to find new meaning in their experiences so that they are more reflective of the type of personal life story that people would like to author (White & Epston, 1990). Narrative therapy has been informed by narrative theories of personality in many ways. For instance, the narrative approach to personality compels therapists to consider how the process of re-framing one's experiences can affect not only their well-being, but also their behavior, and perhaps even their personality more broadly. This suggests to therapists that they should consider more closely the kinds of self-narratives that were deemed positive (e.g. the extent to which these narratives should be "truthful," internally-consistent, or reasonably representative of reality), with a fuller appreciation of the consequences of re-framing one's life story (Angus & McLeod, 2004; McAdams, 1996).

Criticism

Critics of a narrative approach to personality challenge the assumption that it is natural for people to understand the self in terms of narrative. The narrative style that many scholars take is argued to be a Western style of organizing the self-concept, whereas sequential narrativization may not be a customary and productive means of self-expression and conceptualization for people from diverse cultural backgrounds (Polkinghorne, 1996). Other critics argue that some narrators and audiences are limited in their capacity to construct and build on elements of narrative due to restrictions imposed on them by their social positions, affordances of linguistic codes in which they operate, and social conventions and dominant discourses of the settings in which stories are lived and told (Pavlenko, 2002). For this reason, any narrative approach to psychology must be attentive to the fact that certain narrative styles are privileged over others, and therefore a narrative approach is subject to the influence of power structures and may even lead to the disenfranchisement of certain individuals (Pavlenko, 2002).

Conclusion

The narrative approach to personality allows psychologists to understand and explain the relationship between storytelling and self-concept. It also frames the individual as ever-changing and evolving. On the other hand, this approach has many challenges, such as the degree to which forming a narrative identity can be understood as a universal human practice. Nevertheless, it has many implications for the study of personality, and informs related areas of inquiry such as therapy and counseling. The narrative approach to personality represents an exciting direction in psychology, and will likely shape the field for years to come.

Openness

David J. Sparkman

University of Wisconsin–Eau Claire

Definitions of Openness

Openness to Experience is one of the major dimensions of personality in the Five Factor Model (or "Big Five"). Despite its inclusion in the Big Five framework, Openness is the most unreliable and difficult dimension to capture because of its broad, loosely defined structure. At its most concrete level of description, Openness captures the individual who is a creative and divergent thinker, frequently enamored by aesthetic experiences (e.g. art, music, beauty). At its broadest level of description, Openness captures the mystical person prone to experiences of *déjà vu*. In general, highly open individuals are intellectually curious, have rich imaginations, experience a broader range of emotions, and actively seek out diverse and varied experiences. In contrast, closed individuals are conventional, cognitively rigid, comfortable with routine, and uninterested in novelty (McCrae & Sutin, 2009).

Theoretical Background of Openness

The Openness dimension was developed from a rich theoretical tradition of related, but ultimately separate, factors of personality (McCrae & Costa, 1997). Historically, Openness has also been referred to as *Culture*, *Intellect*, and *Intelligence*. Although Openness is partly defined by intellectual endeavors, it is broader than the educated sophistication associated with *being cultured*. To some extent, intellect reflects the cognitive ability component of Openness, but Openness is more than being *able* to analyze and think flexibly – it is the *enjoyment* of doing so across a range of diverse and varied topics. Moreover, there are other traits of the open individual that are inherently non-cognitive, including aesthetic sensitivity and intense, emotional variety. While there is some overlap between the Openness dimension and general factor intelligence, correlations between the two are either weak or modest, suggesting they are not equivalent constructs. More contemporary theories characterize Openness as an intrapsychic personality dimension reflecting "the breadth, depth,

and permeability of consciousness, and in the recurrent need to enlarge and examine experience" (McCrae & Costa, 1997, p. 826).

Measurement of Openness

Openness has been measured in different ways, primarily as a function of two relatively independent traditions within personality theory and research. The lexical tradition suggests human personality is reflected in the vast descriptions of trait adjectives used in natural language. When measuring personality, early lexical traditions included a series of single-trait adjectives to which individuals respond. For Openness, participants indicate the extent to which trait adjectives such as "imaginative" and "intellectual" describe the self. In contrast, the questionnaire tradition of personality measurement uses full sentences that place trait adjectives within context. Participants indicate the extent to which they might "Enjoy wild flights of fantasy" or "Carry the conversation to a higher level." Together, all questionnaire items from this Openness dimension are separated within six subdimensions, or *facets*: Openness to Ideas, Fantasy, Aesthetics, Actions, Feelings, and Values. More recent advances in personality measurement have created somewhat of a hybrid of both the lexical and questionnaire traditions. With a shorter scale, the Big Five Inventory uses short, contextual phrases that also include trait adjectives. Example Openness items include, "I see myself as someone who... likes to reflect, play with ideas; ... has an active imagination." All three approaches to measuring Openness (and the Big Five in general) are highly correlated and show substantial factor convergence.

Stability vs. Change of Openness

Openness to Experience is a strongly heritable dimension of personality, and the covariation among facets is explained at the genetic and phenotypic level. Openness is also remarkably stable across time (Terracciano, Costa, & McCrae, 2006), although other evidence suggests there are consistent patterns of mean-level change throughout the lifespan. Openness increases sharply from adolescence to early adulthood, increases slowly throughout middle adulthood, and ultimately decreases in old age. When personality changes throughout the lifespan, it often does so as a function of changes in social roles, norms, or experiences (Roberts, Walton, & Viechtbauer, 2006). Self-ratings of Openness have been shown to increase due to experiences with other cultures among college students, mystical experiences with hallucinogens among adults, and cognitive training in older adults. Future research is needed to examine whether these and other effects point to an influence of one's social context on shifts in Openness (either temporarily or across time).

Gender and Cultural Differences in Openness

At the factor level, research suggests there are no consistent gender differences in Openness. However, more nuanced analyses at the facet level have found gender differences in Openness that are generally consistent with gender stereotypes. Females typically score

higher on the Openness to Feelings facet, whereas males score higher on the Openness to Ideas facet. Mean levels of Openness also seem to vary in systematic ways across countries and cultures. Though between-culture differences are generally smaller than within-culture differences, self-report and observer-rating studies show French-speaking Switzerland, German-speaking Switzerland, Germany, Austria, and Serbia score highest in mean levels of Openness, whereas Croatia, Spain, Hong Kong, Malaysia, and India score lowest in Openness. Mean, or aggregate, levels of personality may reflect the culture's *ethos*, such that cultures higher in Openness are generally progressive, humanistic, and free-thinking; and those lower in Openness are generally conservative, traditional, and religious (McCrae & Sutin, 2009). Some have argued socio-cultural environments shape the personality of its inhabitants. Given the strong genetic influence on personality, others have suggested the traits of collective people ultimately shape their own culture. More research is needed to address this question.

Micro-social Influences of Openness: Mental Health, Well-Being, and Interpersonal Relationships

Openness has several micro-social influences on the individual, including mental health, well-being, and interpersonal relationships. The influence of Openness on mental health is not as obvious as other dimensions of personality, such as Neuroticism and Extraversion. Some features of Openness may contribute, for example, to schizoid/schizotypal personality disorders (e.g. dull, blunted affect; eccentric fantasies) or obsessive-compulsive personality disorder (e.g. extreme cognitive or behavioral rigidity). However, empirical evidence generally does not support a relationship between Openness and specific psychopathologies. Its influence is relatively weak (compared to other Big Five dimensions), but Openness does have an association with more general outcomes such as subjective well-being. Open individuals tend to be happy, have a high quality of life, and frequently experience positive but not negative affect. Contemporary theories, however, suggest open individuals have a vast emotional repertoire, including not only frequent and intense positive emotions but also negative ones. Future research might look to further investigate the structure of the Openness to Feelings facet and its association with both positive and negative affect.

Openness also exhibits a characteristic pattern of influence on interpersonal interactions and relationships. Open individuals are often perceived by others as humorous, verbally fluent, and expressive, and first impressions of Openness are particularly difficult to change because people assume such traits stem from ability rather than motivation. When meeting new people or developing acquaintances, open individuals tend to be more other-focused (as opposed to self-focused). They visually attend to their interaction partners and spend little time talking about themselves. Closed individuals expect interpersonal interactions to be normative and conventional, and they become uncomfortable or irritated when these rules are violated.

People often self-report desiring a romantic partner that resembles them most on the Openness dimension, but research suggests personality is typically uncorrelated between romantic partners. There are, however, several relationship benefits experienced by highly open individuals, including greater relationship satisfaction, more effective

communication styles, and the ability to target and resolve conflict when it arises. In contrast, closed individuals tend to avoid relationship conflict and employ distancing strategies (often to the detriment of the relationship). In family settings, open parents are more egalitarian in sharing parental roles, whereas closed parents are more hierarchical and differentiate parental roles according to traditional gender roles. Open parents typically respond to their children with warmth and allow them to have self-direction; closed parents expect obedience and rule-following (McCrae, 1996; McCrae & Sutin, 2009).

Macro-social Influences of Openness: Social Attitudes, Political Ideology, and Values

Of the Big Five dimensions of personality, Openness shows the strongest and most consistent pattern of influence on macro-social attitude and belief structures. Highly open individuals value unconventional, open-minded thinking and express tolerance of diverse viewpoints, people, and cultures; closed individuals prefer tradition, conventionalism, and have a penchant for loyalty to the ingroup. Openness – at the factor level and across most of its facets – is consistently and negatively correlated with generalized prejudice (e.g. gender, sexual orientation, race/ethnicity). Recent evidence, however, suggests this well-documented relationship between Openness and prejudice depends on the perceived (un)conventionality of the target group. Those high in Openness prefer more egalitarian societies, whereas those low in Openness are found to be higher in right-wing authoritarianism, a broad ideology in which security, order, and ingroup cohesion function to defend against a world seen as dangerous and threatening. These broad, underlying social-ideological attitudes typically manifest themselves at the level of political affiliation and voting behavior. Of the Big Five dimensions, Openness is strongly and consistently related to political orientation. Those high in Openness tend to be liberal and vote for the Democratic Party (United States), whereas those low in Openness tend to be conservative and vote for the Republican Party (McCrae, 1996; McCrae & Sutin, 2009). At the most basic level of values, Openness is strongly associated with self-direction (creativity, independent thought), stimulation (excitement, novelty in life experiences), and universalism (global equality, protecting the environment).

Optimism/Pessimism Carver and Scheier Theory

William D. Marelich and Brooke Piercy

California State University, Fullerton

> *Man often becomes what he believes himself to be. If I keep on saying to myself that I cannot do a certain thing, it is possible that I may end by really becoming incapable of doing it. On the contrary, if I have the belief that I can do it, I shall surely acquire the capacity to do it even if I may not have it at the beginning.*
>
> **(**Mahatma Gandhi)

> *Christopher Robin: "There now. Did I get your tail back on properly, Eeyore?" Eeyore: "No matter. Most likely lose it again anyway." (Winnie the Pooh and the Honey Tree)*

Conceptualized

Claire is in good health, both mentally and physically. She has an upbeat disposition, looks on the bright side of situations, and is positive about things going her way (much like Mahatma Gandhi's quote). Joseph, on the other hand, is constantly stressed at work and in his home life, and has physical issues with his lower back. When faced with uncertain situations, he rarely expects positive outcomes, is often dour, and thinks negatively about the future (much like the character Eeyore noted above from *Winnie the Pooh and the Honey Tree*).

In the above examples, Claire is an *optimist*, exuding an air of optimism in her life and surroundings, while Joseph is a *pessimist*, conveying an air of pessimism as he moves through life. When we speak of optimism/pessimism, what exactly are we referring to? How might optimism/pessimism influence well-being and mental/physical health outcomes? Claire's health is superior to Joseph's, suggesting a possible relationship between being an optimist/pessimist and one's mental and physical health. Based on research, is there such a relationship?

The concept of optimism (and pessimism) is a prevalent research topic in the fields of health psychology and positive psychology, both in terms of direct research on the topic,

and in terms of a measureable dispositional trait for applied research. However, long before its formal establishment in the 1980s (Scheier & Carver, 1985), the concept of optimism/pessimism was part of the everyday or naive psychology lexicon (see Heider, 1958, for a discussion of naive psychology), where individuals strive to make sense of the world and their surroundings and thus create their own theories of cause and effect. To help make the world a predictable and pleasant place, we might view those who are optimistic as appearing more happy and healthy, while those who are pessimistic are viewed as complaining and ailing. To the average person, optimistic individuals are more pleasant to be around and seem more empowered ("Claire is so optimistic and positive – what a joy to be around!"), while those who are pessimistic may seem unhappy and may not be one's first choice to socialize with ("Joseph is such a downer – it's such an effort to hang-out with him").

Beyond everyday or naive psychology conceptualizations, in the 1950s social/behavior science formally began evaluating concepts related to optimism/pessimism, with research addressing issues such as psychological well-being and life satisfaction. Decades later, more formal work on the topic was offered by Scheier and Carver (1985), who directly conceptualized optimism as a dispositional trait. Theoretically, the concept of optimism grew out of Scheier and Carver's model of behavioral self-regulation, which was influenced by general expectancy-value theories in psychology (see Scheier & Carver, 1988, for a brief overview of their model of behavioral self-regulation). Simply put, individuals who overcome adversity in goal obtainment are those who expect to reach their goals. As long as there is a positive expectancy for success, the individual will continue to strive for goal attainment. Scheier and Carver summarize a number of studies that illustrate the effects of favorable expectancies toward a desired outcome. As they summarized their findings, they ultimately found that what they were developing was a framework for dispositional optimism.

Optimism is also viewed as triggering active coping strategies. In particular, optimism positively influences problem-focused coping (i.e. motivation to engage the problem, confidence to solve the problem), and seeking social support behaviors (i.e. support from family, friends, and other social ties, inclusive of tangible, informational, and emotional support). It also enhances a sense of personal control.

Life Orientation Test (LOT and LOT-R)

Much of the popularity of the optimism stems from Scheier and Carver's *Life Orientation Test* (LOT; Scheier & Carver, 1985). Prior to 1985, Scheier and and Carver were in the midst of developing their model of self-regulation. As they aggregated their research and started to make progress on the concept of optimism, an assessment tool was required. As they note in 1985, "we found ourselves wanting a measure of what we take to be dispositional optimism" (Scheier & Carver, 1985, p. 223). Thus, the LOT was developed as a way to assess a generalized sense of optimism.

Although widely used, there were a number of criticisms of the LOT. In particular, there was a need to make the LOT more predictive of outcomes, and to insure items focused on expectations of positive outcomes. After these few changes, the LOT-R (Life Orientation Test – Revised; Scheier, Carver, & Bridges, 1994) was published. The LOT-R has strong psychometric and predictive qualities, and is widely used today to assess optimism.

Predictive Qualities

Optimism has been shown to be predictive of both mental and physical health outcomes (i.e. biopsychosocial outcomes). Regarding mental health, optimists are less likely to report anxiety, depression, and are less neurotic than those who are pessimists. Optimists are more likely to report higher levels of self-esteem, seek social support more often, and have a greater sense of personal control. Regarding physical health, optimists report fewer health symptoms and less pain, increased levels of mortality and survival, more positive physiological markers, and better pregnancy and cardiovascular outcomes (to name a few). Together, these findings, especially mortality and survival rate increases, are extremely important as they reflect behavioral health outcomes and quality of life issues (see Kaplan, 1990, for a discussion concerning quality of life outcomes).

Current Status

What can we conclude about the personal disposition of optimism (and pessimism)? Is the concept useful for applied research, and how does it impact individuals? Currently, optimism may be considered a dispositional trait, accurately predicting a host of positive outcomes for optimists, and negative outcomes for pessimists. As of this writing, optimism and pessimism – as concepts, cognitive expectancies, or viewed more accurately as dispositional trait(s) – are well established.

The added value of being optimistic in terms of both mental and physical health outcomes is unequivocal. In addition to the positive outcomes noted earlier, optimists report in some instances better immune response, fewer upper respiratory illness symptoms and influenza, better coping with chronic ailments, and have greater levels of well-being and hope. Though some downsides have been noted (e.g. greater short-term stress when goals are thwarted; Sergerstrom, 2006), the bounty of positive health and well-being outcomes clearly underscore the advantages of being an optimist over being a pessimist. Indeed, in sharp contrast to findings noted for optimists, outcomes associated with pessimists are rather negative. For example, one dire finding is that pessimists tend to have higher mortality rates (e.g. cancer death rates, death due to old age). In addition, higher rates of morbidity are also noted, including higher blood-sugar levels (a marker for diabetes), hardening of the arteries (related to atherosclerosis), greater reported physical ailments, pain, and fatigue, and worse physical functioning.

Although viewed as a personality disposition, there is some research suggesting optimistic thoughts/attitudes can be manipulated, with optimism actually increased to yield better health outcomes. For example, Mann (2001) conducted a longitudinal study on HIV-infected women to assess if optimistic writing could positively influence their HIV-drug adherence. Participants were asked to write optimistically about a "future" where their HIV-drug regimens were simplified by taking just one medication a day (typically, HIV-infected individuals have complicated drug regimens, taking multiple drugs each day). Participants at the start of the study who scored low in optimism (assessed with the LOT) actually increased their dispositional optimism score by the end of the study, and reported increased drug adherence and less negative affect regarding medication side-effects. This suggests a possible fluidity or at least some relationship between directed optimism and

trait optimism (possibly analogous to what has been termed "little and big" optimism; Peterson, 2000) which has yet to be fully explored, but again underscores the import of optimism for health and well-being.

Overall, Scheier and Carver's work remains robust, and use of the Life Orientation Test-Revised (LOT-R) is widely prevalent. For example, a number of meta-analyses have been conducted on the effects of optimism and pessimism (see Further Reading section), underscoring the established use of the concept. In addition, a *PUBMED* search from the year 2000 through 2016 shows the term "Life Orientation Test" noted over 200 times – thus, dispositional optimism and its measurement is popular among social/behavioral scientists, and is an indelible contribution to a better understanding of individual differences and dispositional traits.

Personal Projects

Brian Little and Sanna Balsari-Palsule

University of Cambridge

Origin and Definition

Personal projects are the fundamental building blocks of our daily lives. They can be diverse in nature, ranging from apparently trivial pursuits (e.g. take the dog for a walk) to transformational undertakings (e.g. help my wife rediscover her sense of purpose). Little (1983) first introduced personal projects as a theoretical response to the integrative challenges of the person-situation debate. Personal projects are a tractable unit of analysis in which features of both individuals and their embedding contexts interact as dynamic influences on individuals. The corresponding methodology, personal projects analysis (PPA), captures rich information and "thick" descriptions of the internal motivations and external hindrances and affordances of human action. PPA has made significant contributions to the social sciences (e.g. personality, social, developmental, and organizational psychology) and fields ranging from rehabilitation therapy to moral philosophy (Little, 2014; Little, Salmela-Aro, & Phillips, 2007).

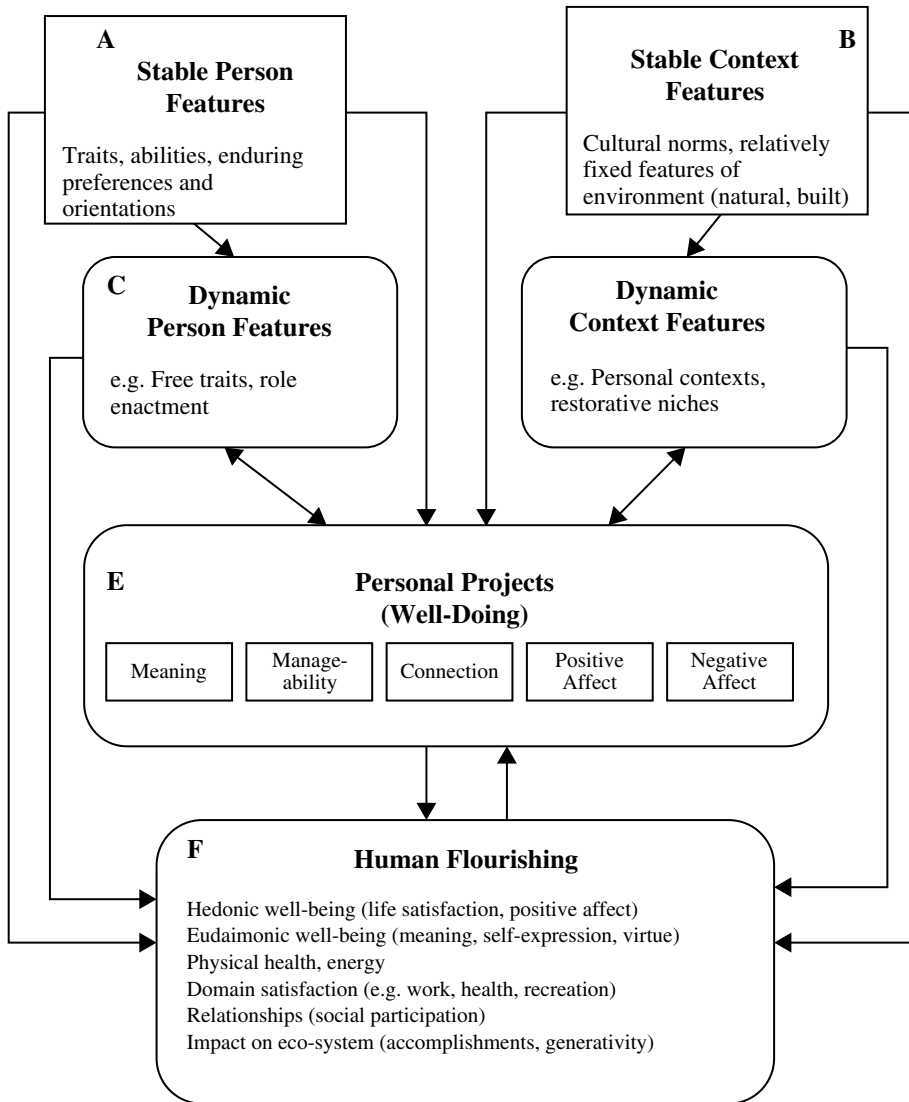
Personal projects are formally defined as "extended sets of personally salient action in context" (Little, 2007, p. 25). Conceptually, personal projects are personal action constructs (PAC units) that occupy a middle level of analysis in hierarchical models of personality (Little, 1999, 2006; Little, Lecci, & Watkinson, 1992). Another distinctive feature of personal projects is their roots in a social-ecological model of human development (Little & Ryan, 1979), depicted in Figure 1. The social-ecological model illustrates the processes by which well-being and quality of lives are influenced by dynamic and stable features of both persons and environments. A central postulate of this model is that personal projects serve a critical role as a transactional conduit or "carrier unit" of person and environments, and can therefore, directly and indirectly enhance well-being and the quality of lives.


Figure 1 Social-ecological model of human development (B. R., Little, 2014. Well-doing: Personal projects and the quality of lives. *Theory and Research in Education*, *12*, 329–346).

Measurement of Personal Projects

PPA is a multi-modular instrument that assesses the content, appraisal, and impact of personal projects via four modules (Little & Gee, 2007). Its uniqueness lies in its seamless adaptation to the researcher's line of inquiry and theoretical focus. PPA is typically administered in written form (i.e. printed or online), although it can be adapted to an interview format for clinical and/or intensive research purposes.

Project Elicitation

In the first module, individuals are presented with examples of personal projects and prompted to list their ongoing or planned personal projects. Typically, participants list around 15 projects with those high in openness to experience tending to generate more. The content of listed projects can be analyzed using traditional content and categorization analysis. Eight categories from different domains of activity are frequently discerned: e.g. academic or work (e.g. complete my assignment), interpersonal (e.g. call mom on Skype), intrapersonal (e.g. be a more giving person), leisure/recreational (e.g. meet Terry for coffee), health (e.g. get fit), maintenance (e.g. file paperwork) and others. Beyond project content, personal projects can be analyzed at the level of the phrasing and syntax in which they are expressed. Indeed, linguistic analyses have found that personal projects expressed as "trying to" or "avoiding" were less likely to be successful and associated with lower well-being (Chambers, 2007).

Project Appraisal

After listing their projects, respondents select a subset of their projects (usually 10), and appraise each project on a set of dimensions (rated on a 0–10 scale). In the original version of PPA, the appraisal matrix consisted of 17 standard dimensions and two-open ended questions on "with whom" and "where" the project is carried out. These dimensions were drawn from important theoretical constructs in psychological research. Over time, novel theoretical propositions and factor analytic procedures have led to the emergence of five major themes from these dimensions: (1) Meaning (e.g. self-identity, value-congruence), (2) Manageability (e.g. control, efficacy, progress), (3) Connection (e.g. visibility, importance as viewed by others, support from others), (4) Positive Affect and (5) Negative Affect. Cumulative research evidence suggests that people experience greater well-being when their projects are meaningful, manageable, connected with others, and associated with more positive affect than negative affect (Little et al., 2007).

A key foundational feature of PPA is its modular nature. Unlike traditional psychological assessment, PPA adapts to the social ecologies of its respondents and encourages the use of *ad hoc dimensions* to measure a theoretical construct of interest, a specific individual or eco-setting. Over the last 30 years, hundreds of *ad hoc* dimensions have been implemented in studies of diverse groups such as adolescents, middle-aged men, senior executives, pregnant women, entrepreneurs, college students, anorexic patients, and post-stroke patients. These ad hoc dimensions are frequently unique predictors of well-being and human flourishing. As in the elicitation module, PPA enables numerous analytic procedures in the appraisal matrix. Researchers can conduct both idiographic and normative analysis. In idiographic analysis, researchers can examine the correlations between two appraisal dimension scores and average the scores across all personal projects to provide a mean score representing the global state of a person's personal project system. This information can be aggregated to normative and comparative levels as mean scores can examine the relation between project-level between-person variation and other characteristics (e.g. personality traits).

Cross Impact-Matrix, Joint Cross Impact-Matrix, and Hierarchy Modules

The Cross-Matrix and Joint-Cross Matrix are an optional set of modules that offer researchers deeper insight into the impact of personal projects. By calculating the impact each project has on others in the matrix, the degree of conflict or complementarity can be assessed. The Joint Cross Impact-Matrix follows a similar logic to the Cross Impact-Matrix except it examines the impact of another person or group on an individual's project system (Little & Gee, 2007).

Personal projects are a middle-level unit, occupying the position below molar-level superordinate goals and values, and above molecular-level schedulable acts (Little, 1999). The hierarchy module addresses the linkages between these three levels. Using a laddering form, individuals are repeatedly asked why they engage in each of their projects and this iterative process continues until the answer becomes an end in itself. Each answer is considered a rung on a ladder so that the number of ladder rungs measures of the distance of a project from a schedulable act ("'How' laddering") or over-arching goal ("'Why' laddering"). The hierarchy module explains the "meaning-manageability trade-off" quandary; why some projects may be easily achievable as acts, but lack meaning and others carry vast personal importance, but are unmanageable (Little, 1998).

Representative Research

Since the 1970s, the body of empirical evidence on personal projects has been steadily growing. The majority of data is stored in the Social Ecological Assessment Databank (SEAbank), an electronic database that is updated periodically. Much of the research has examined the effects of project variables (e.g. project categorization, content, appraisals, and dimensions) on well-being. Research has confirmed that affective and cognitive features of personal projects and the sustainable pursuit of core projects contribute to well-being and human flourishing (Little, 2016). Another segment of research has illuminated the pathways between key elements in the social-ecological model of human development and project pursuit. Research has established direct links between the Big-Five traits and project appraisals, with Conscientiousness as the strongest predictor of positive project appraisal and Neuroticism linked to negative project appraisal (Little, Lecci, & Watkinson, 1992). Personal projects also serve as a vehicle for the influence of traits on well-being. A sense of efficacy in one's personal projects (i.e. a key dimension in Manageability) mediates the link between Neuroticism, Openness to Experience, Conscientiousness, and Agreeableness on subjective well-being (Albuquerque et al., 2013).

Further examples of the linkages with the social-ecological model include the effects of contexts and societies on project pursuit. Interdisciplinary studies have shown that project pursuit can be thwarted by environmental features (e.g. noise annoyance) but advanced by the perceived supportiveness of the environment. When viewed in the context of the social-ecological model, human flourishing comprises the sustainable pursuit of core personal projects (Little, 2015).

New Directions in Theory, Methodology and Application

Research on the social ecology of personal project pursuit is expanding in several areas. The integrative role of personal projects as analytic units in both psychology and philosophy is being actively studied (e.g. Betzler, 2013; Little, 2014).

There are also increasing calls for integrative and explanatory theories within personality psychology. One promising focus would be on tracking the links between personal project theory and "whole trait" theory that views the manifestation of traits as personality states (Fleeson & Jayawickreme, 2015). Variation in personality states is also conceptually linked with *free-trait theory* that is central to the social-ecological model (Little et al., 2007). This theory proposes that individuals enact certain traits (i.e. "act out of character") to strategically advance the pursuit of their core personal projects, which can both promote but also hinder well-being. Although empirical evidence has provided initial support for free-trait theory, expanded studies are underway. These studies offer deeper insight into the specific categories and content of projects that propel individuals to enact certain traits, and the effects of acting out of character on outcome measures beyond well-being (e.g. productivity and job performance).

Finally, rapid technological advances in the implementation and utilization of psychometric testing on social media and virtual platforms are spurring new, creative ways of presenting PPA on novel platforms. Similarly, there are great leaps anticipated in the emergence of newly-designed PPA tools that are applicable in organizational, counseling, and community contexts. With widespread changes to traditional performance management, personal projects analysis assumes increasing importance in performance feedback and personal development discussions. As PPA provides a means of changing how individuals construe and manage their contexts, PPA tools provide a way of both explaining and enhancing the quality of human lives.

Personality and Language

[3] *Lancaster University*

Characterized and Conceptualized

Language, broadly defined, includes both the words people use and the ways in which they are used. Research on language and personality has found that various patterns in a person's language can reveal a great deal about their underlying psychological composition. In other words, each person's unique language patterns contain embedded clues about their stable individual characteristics. Psychological measurements of language tend to exhibit robust, trait-like properties that have been widely used as a mode of exploring personality and other psychological constructs.

The increasing use of quantified language in personality research is principally due to the consistent relationships established between the two domains. By analyzing patterns in language samples (e.g. essays, speeches, interviews, recorded conversations, etc.), researchers are able to establish an individual's *linguistic profile,* a cluster of unique language patterns that is predictive of psychological composition. This linguistic profile can be used to understand and assess personality by conducting research on linguistic tendencies that correlate with, or are indicative of, personality across various research designs. For example, language patterns can vary as a function of depression, social status manipulation paradigms, or self-reports of personality. Relatedly, language-based measures are often used to predict and understand personality-relevant variables of interest, such as demographics (e.g. sex, age, level of education), behaviors (e.g. cigarette smoking, aggression), and other individual differences (e.g. decision-making patterns, trait affect, motivational processes).

Research has found that language is a valid and reliable way to explore personality, individual differences, and lower-level processes that drive such constructs. Several empirical studies have demonstrated that the various ways in which people express themselves through language are stable and consistent within an individual across time and context.

The most common way that personality research is conducted using language measures is by establishing statistical relationships between quantified measures of language use and other measures of personality. Studies in this area often rely upon traditional measures of personality (e.g. self-report measures, behavioral outcome measures) and have found that various categories of language show consistent relationships with such personality measures, suggesting that language can serve as an unique mode of analyzing personality (sometimes referred to as Language-Based Assessments, LBA, or L-data). Furthermore, research has also shown that language-based measures of personality are able to capture personality characteristics that are not easily captured by self-report measures due to factors such as self-report biases and accessibility. This is partly due to the fact that language production involves several automatic, low-level generative processes into which humans lack accurate self-insights.

The ways in which language can be measured/quantified for use in personality research are diverse, ranging from the rate at which a person uses purely syntactic categories of speech to words with inherent semantic value, average word length, and frequency of verb tenses, among other approaches. The comprehensive analysis of language includes quantifying both a person's language *style* in addition to their language *content*. Language *content* represents the "what" of a language and primarily consists of semantically-laden words (e.g. emotion words, social words). Language *style* primarily consists of function (i.e. syntactical) words (e.g. prepositions, conjunctions). Language content typically include words classified as nouns, regular verbs, and most adjectives and adverbs – words that generally have meaning even without context, such as "happiness" or "family." Function words primarily include pronouns, prepositions, articles, conjunctions, and auxiliary verbs, among other classes of linguistic particles – words that do not possess inherent meaning without context, such as "of" and "the."

Function and *content* words often show different personality correlates. Content words most commonly exhibit statistical relationships to explicitly-accessible self-information, such as sociability and trait affect, whereas function words are typically predictive of lower-level personality processes, including things like automatic cognitive and attentional processes.

Language Analysis Methods and Techniques

Qualitative Methods

Language analysis in psychology dates back to the early beginnings of modern psychology. The earliest research methods of psychological language analysis were qualitative methods. Early work on language and personality principally consisted of case studies that emphasized the deep interpretation and discovery of hidden meanings in a person's language. Such methods include classical projective tests developed by Rorschach and others to discover people's thoughts, intentions, and motives from their verbalized interpretations of abstract images such as inkblots, as well as Murray's Thematic Apperception Test (TAT), which was designed to reveal information about a person's implicit motivational processes.

The main disadvantages of qualitative approaches to language analysis are that a researcher's subjective interpretation of language data may often introduce non-uniform bias, and the findings cannot typically be extended to wider populations with the same degree of certainty as quantitative analyses. Qualitative approaches to language analysis are not commonly used in modern empirical personality research, but several such methods do still exist and have demonstrated value in research and clinical practice. Qualitative methods may be viewed as the foundation upon which more objective empirical methods have been built; such methods remain an implicit component of many language analysis techniques.

Manual-Based Language Coding

Many approaches to language analysis research require multiple human raters to manually code texts. These approaches typically employ human judges that rely on standardized manuals in order to identify and quantify prevalent themes and patterns within a sample of participant language. These approaches use language to explore personality characteristics by coding latent constructs such as motivational processes, intimacy, explanatory style, gregariousness, and decision-making, among others. Manual-based coding techniques are also sometimes applied to aid in the diagnosis of clinical phenomena, such as personality disorders.

Based on formalized coding systems, manual analyses can be used to explore whether a particular theme is indicative of certain personality constructs. For example, some findings show that manually-coded themes about "status" suggest a striving for power, and other studies show that people's explanatory styles (the ways people explain the cause of an event) are linked with optimism, depression, and habitual health behaviors. The primary drawback of manual text coding is that studies can suffer from issues of inter-rater reliability and a reliance on subjective judgment calls in cases that are not adequately covered by coding manuals. Nevertheless, the manual-based coding of language can be particularly useful for small samples and difficult-to-assess constructs that require advanced knowledge to recognize. Manual methods continue to be a mainstream mode of exploring language within psychology, and such methods allow researchers to closely understand the language samples in their studies.

Automated Text Analysis

With the technological advances of recent decades, automated text analysis methods have begun to replace traditional ones with increasing frequency. Automated text analysis gained popularity primarily as a result of the expansion of the internet and a sudden availability of language samples that were too large to code manually. Much like manual coding, automated text analysis methods quantify a person's language for the purpose of better understanding underlying psychological patterns. Most automated text analysis systems use *word counting* approaches, where sets of words are clustered into construct-specific dictionaries (e.g. affective words, morality words, risk-sensitivity words). Texts are then

scanned for words in these dictionaries, and categories of words are then scored for their relative frequency (e.g. 10% cognitive words, 4% positive emotion words). The creation of dictionaries that exhibit acceptable psychometric properties is a difficult task, and this has been cited as the major drawback of dictionary-based text analysis approaches.

Automated theme extraction, or *topic modeling,* refers to a family of methods that use a bottom-up approach to discover what topics or themes exist in a collection of documents. These methods typically aim to determine the inherent themes of the texts and can be used to categorize language samples. Most topic modeling approaches consist of some variation of generating statistical models designed to capture concept co-occurrence (e.g. "beach" and "sand" may commonly co-occur, as might "lawyer" and "divorce"). These methods most often express themes as a latent construct that can be mathematically approximated from the words that people use. Other latent model methods, such as Latent Semantic Analysis (LSA), are conceptually related to topic modeling methods and are typically used to extract meaning from texts by modeling the proximity of word use in addition to the similarity of various words and phrases. Methods such as topic modeling and LSA are considered "bottom-up" approaches to automated text analysis as they are data-driven, rather than the "top-down," dictionary-based methods that rely on premade dictionaries. Whereas top-down methods of language analysis are limited in scope but typically theory-driven, bottom-up methodologies are more broadly applicable but largely exploratory.

The objectivity and reliability of computerized language analysis corrects for several issues inherent to qualitative and manual coding methods, however, other drawbacks exist that are better addressed via non-automated coding. A primary challenge in automated text analysis lies in the difficulty of automatically modeling language that is sensitive to context or can take on alternative meanings. Sorting words into clusters can be difficult due to issues of homography, wherein many words are spelled identically but have multiple meanings and different connotations depending on when, where, how, by whom, and toward whom they are used. For example, the common word *like* may express evaluation or approval ("I *like* that song"), similarity ("This car is *like* that one"), or be used to serve as a filler word ("I am, *like*, really happy"). Computerized dictionary-based approaches are generally unable to detect subtle aspects of language such as irony or metaphors, which are potentially important psychological constructs for personality research.

While most personality research involving automatic language analysis quantifies the relative frequency of various predefined words/thematic categories, methods hailing from other traditions, such as information sciences or computational linguistics, have been successfully applied to personality research as well.

Dimensions of Language in Personality and Personality Processes

Several studies have established stable associations between personality traits and the types of words people use, allowing researchers to accurately estimate/predict a person's distinct personality traits by analyzing their language. For example, as hypothesized, individuals who score high in self-reported extroversion more frequently use words indicative of social processes (e.g. friend, talk, husband). Self-reported openness is usually marked by an

elevated use of articles and words related to insight (think, know, consider), and conscientiousness is indicated by a person's infrequent use of negations and negative emotion words.

Importantly, more atomic facets of personality, or *personality processes*, are often more directly encoded in a person's language than broader personality constructs. Personality processes are the lower-level facets of behavior, cognition, and affect that contribute to the broader, overall personality constructs. These processes include any psychological mechanism that is stable over time and cohere to form, or contribute to, personality. For example, many low-level social processes are indicative of broader personality traits. A tendency to mitigate social conflict contributes to the broader trait of agreeableness, and elevated positive affect during socialization is a process that contributes to extroversion. Relatively low use of anger words during conflict may be predictive of an agreeable peace-keeper, and an increased use of positive emotion words during socialization can mark an extrovert's affective processes in trait-congruent contexts.

Relatedly, cognitive processes that contribute to personality show language embeddings as well, typically in the form of function words. Frequent use of first-person singular pronouns (e.g. "I," "me," "my") is reflective of self-reflective attentional processes that are markers of neuroticism and depression. Thinking styles (e.g. slow and deliberate versus fast and non-conscious) are reflected through function word use as well, and such cognitive processes can be indicative of personality variables as diverse as conservatism, attributional tendencies, and self-schemata.

Personality Stability and Change over Time

Sarah E. Hampson and Lewis R. Goldberg

Oregon Research Institute, Eugene, Oregon

Freud believed that personality is largely formed by the age of 5 years, and William James said that personality sets like plaster by age 30. More recently, personality psychologists estimated that personality becomes stable by about age 50, although it may undergo further changes later in life. Indeed, instead of trying to identify when personality stops changing and achieves stability, the pendulum has swung in the direction of understanding the more complex idea of the interplay between personality stability and change across the entire lifespan.

Empirical studies of personality stability and change typically investigate personality traits, defined as relatively enduring patterns of thoughts, feelings, and behaviors. To measure these patterns reliably and to use them to predict future outcomes depends on their being somewhat stable. Without some degree of stability, neither scientists nor laypersons would find traits useful for describing people or understanding their behavior. However, just as height increases until young adulthood, then remains stable until a decline in old age, psychological capacities, including personality traits, may also follow a trajectory of development, stability, and change.

Personality psychologists have examined such a maturational model of stability and change for the Big Five personality traits (extraversion, agreeableness, conscientiousness, emotional stability, and intellect/openness). They have confirmed that, just like our physical development, personality traits undergo marked changes in childhood and youth, then stabilize in adulthood before changing again in old age (Specht et al., 2014). Broadly speaking, there is a general trend for personality traits to mature in a more socially desirable direction. In a landmark study, Roberts, Walton, and Viechtbauer (2006) compared mean levels of Big Five traits in samples that differed by age. Comparing samples across different ages, they found that people became less neurotic, and more dominant (a part of extraversion), agreeable, and conscientious, whereas in old age they became less open to experience and less social (another aspect of extraversion). In addition, some studies show that after age 60 people become less conscientious as they leave work responsibilities behind and enjoy "La Dolce Vita" (Marsh, Nagengast, & Morin, 2013).

Another way to study personality stability is by rank-order correlations. These correlations measure the degree of similarity between levels of the same trait across two occasions. They indicate the extent to which individuals maintain their rank-order position across two times of measurements. For example, is the most extraverted adolescent freshman in high school also the most extraverted senior? These correlations range from 0–1.0, where zero indicates the rank order of sample members on the first occasion bears no resemblance at all to the rank order of the sample on the second occasion, and 1.0 indicates the identical rank-ordering of the sample members on both occasions. Not surprisingly, given the findings for substantial maturational changes in childhood and youth, these correlations are lower for children than adults across the same time interval, but are far from negligible. In another landmark report combining results from numerous studies, Roberts & DelVecchio (2000) estimated the rank order stability correlations across the same time interval for samples of different ages. For children aged 6–12 years, this estimate was between .40 and .50, whereas for adults aged 50–59 it was over .70. In sum, when personality is still developing, it is considerably less stable than when it has reached maturity in adulthood, although even then it is not perfectly stable.

The study of rank-order correlations has also established that longer time intervals between the two personality assessments result in lower correlations. This is true when examining time intervals within adulthood, so is likely to be even more marked when correlating an assessment in childhood, when personality is still developing and is therefore unstable, with an assessment in adulthood. In a study of Big Five stability over 40 years from approximately ages 10 to 50, the highest rank-order correlation was only .30 for extraversion, and emotional stability correlated .02, indicating no stability at all (Hampson & Goldberg, 2006). This study underscored the importance of examining differences in trait stability among the Big Five: some personality traits appear to be more stable than others.

Combining the findings from these two ways of studying personality stability, it is apparent that there are maturation trends that result in average trait levels changing over time but within these normative trends, individuals remain at least moderately consistent, and more so in adulthood than in childhood. As insight into this pattern of personality development emerged, it prompted considerable interest in the causes of personality stability and change over time. One view is that personality change over the lifespan is primarily the result of intrinsic maturational changes brought about by genetics (McCrae & Costa, 2003), while another is that it results from encountering and adapting to life experiences (Roberts, Wood, & Smith, 2005). Most recently, the study of genetic and environmental influences on personality traits incorporates the concept of epigenetics, the idea that life experiences cause genes to be activated or suppressed, into socio-genomic personality theory (Roberts, 2018). The discovery of epigenetics tells us that biology is not necessarily destiny, and it becomes even more challenging to unravel the genetic from the environmental components of personality traits.

The life events most commonly thought of as leading to personality change are those social milestones related to love and work. Young adulthood (i.e. before about age 30), is a time of considerable personality change, and also a time when there are cultural pressures to enter into a stable relationship and settle on a vocation. More broadly, across the lifespan, experiences related to love (e.g. marriage, parenthood, divorce, and widowhood) and experiences related to work (e.g. going to college, getting a first job, becoming

unemployed, and retiring) are expected to lead to changes on Big Five traits. It seems reasonable to expect that a person may become more conscientious after joining the workforce, or more agreeable after finding a romantic partner. However, existing studies provide only modest support for these commonsense ideas (Bleidorn, Hopwood, & Lucas, 2018). This may be due to the lack of adequate longitudinal research, which requires assessing personality before and after major life experiences that are beyond the researcher's control.

In addition to personality trait change induced by external events, there is the possibility of intentional change attributable to a person's desire to change themselves. As would be expected, psychotherapy produces changes on Big Five traits such as extraversion and neuroticism (Magidson, Roberts, Collado-Rodriguez, & Lejuez, 2014). Many of us would like to change some aspect of ourselves for the better, and so it is reassuring to know that intentional personality change is achievable although not necessarily easy (Hudson & Fraley, 2015).

Personality demonstrates both stability and change, probably less stability and more change than was hitherto believed. What are the implications of this increasing emphasis on personality change over the lifespan for the usefulness of the concept for understanding ourselves and others? One important yardstick for measuring the utility of personality is the extent to which personality traits predict consequential outcomes such as job performance, marital stability, health, and longevity. There is substantial evidence that personality predicts such outcomes, even when assessed many years prior to the outcome in question, including the case where personality is measured in childhood and the outcome is measured in adulthood (Roberts et al., 2007; Moffitt et al., 2011). Early personality traits can have a long-reaching impact on life outcomes, despite subsequent personality change.

Scientific observations of personality changes over the life course may not sit well with our subjective experience of personal continuity. How do we reconcile our enduring sense of self with demonstrable personality change? McAdams (2013) proposed that we do this by constructing our life story in which we make sense of our experiences and changes to form of a meaningful autobiography. We also may underestimate the amount of personality change that has occurred by recalling our past selves as more similar to our present selves than was actually the case.

To conclude, contrary to Freud and others, findings from personality research do not support the view that personality development stops in childhood or young adulthood. Personality traits, like other psychological and physical attributes continue to develop and change throughout life. Before the age of 30 and after the age of 60 are the periods of greatest personality change. These changes result from a combination of genetic and environmental influences that are still poorly understood.

Personality in Culture

Rachele Benjamin and Kate Guan

University of British Columbia

The relationship between personality and culture has sparked much interest among personality and cultural psychologists alike. Theorists have long proposed that there is a core set of personality traits that are universal, as opposed to culturally-bound. However, there is evidence that culture plays a major role in determining one's personality, and may even lead to the expression of traits that are not captured by models of personality developed in Western cultural contexts. Another source of academic interest is the degree to which cultures agree on what personality actually is, and how individuals understand the self and identity. This section explores some of the key theories and findings that have been made in cross-cultural studies, and the implications they carry for how we are to understand the self and personality.

The Concept of Personality Across Cultures

Any discussion of personality in culture must begin with cultural differences in how the self is constructed. One well-established cultural difference is the degree to which people perceive themselves as separate from others, or connected to them. Markus and Kitayama (1991) distinguished between independent, and interdependent self-construals, where people with an interdependent self-construal view themselves as separate, distinct entities from the people around them and individuals with an interdependent self-construal view themselves similar to the people around them. For people with independent self-construals, the self is believed to contain all of the key features of one's identity, including preferences, opinions, and personality. People from Western cultural contexts (i.e. North America, Europe) typically have independent self-construal (Markus & Kitayama, 1991). On the other hand, people from Eastern cultures (i.e. China, Japan) typically have an interdependent self-construal. That is, they believe that many key features of their identity are tied to the relationships they have with others. This creates differences both in terms of how people from different cultural contexts interact with those around them, and how they perceive themselves.

One consequence of this difference is that people from Eastern and Western cultures differ in how consistent their self-concept is across situations. Self-consistency can be thought of as a tension between the concept of a situational self (in which aspects of behavior are affected by the situation) and a stable self (in which a person's behavior is consistent across situations and arises out of their underlying personality). Japanese people, for instance, are much more likely to vary their self-descriptions depending on their social context, and are more self-critical when they are around other people (Kanagawa, Cross, & Markus, 2001). Americans, on the other hand, provide self-descriptions that are invariably positive, regardless of the social situation. This reflects the degree to which the self is inter-related with others in their social context.

Another cross-cultural difference in how people understand identity is between entity and incremental theories of self (Dweck & Leggett, 1988). Individuals who hold an entity theory of self believe that one's traits and personality are unchanging, and reflect some underlying core essence. Entity theorists thus believe that their abilities are fixed, and will stay the same over time. Individuals who hold an incremental theory of self, on the other hand, believe that one's traits and personality are malleable and can be improved over time. Incremental theorists thus believe that skills and abilities can be increased through hard work. Studies provide evidence that East Asians are more likely to hold incremental views of the self than North Americans (e.g. Heine et al., 2001; Norenzayan, Choi, & Nisbett, 2002). This impacts people's attitudes toward success, achievement, and perceived efficacy. Chinese, Japanese, and Indian people are all more likely to believe that intelligence and academic success are the product of hard work, which in turn has been shown to affect people's orientations toward self-improvement. In contrast, North Americans have been shown to increase effort following success, but not following failure (Heine et al., 2001).

Personality Differences Across Cultures

The stability of the self across social contexts, and across time, varies between cultures, as does the degree to which people value individuality or relationships. A separate but related topic is the degree to which personality traits can be thought of as universal, or culturally-situated. For instance, the Five Factor Model of Personality, or Big Five (McCrae & Costa, 1987) is the most widely endorsed model of personality, and is believed to present itself everywhere in the world. In this model, personality is organized into five dimensions: openness, conscientiousness, extraversion, agreeableness, and neuroticism. Researchers have consistently observed differences in the degree to which each of the five dimensions is expressed. Using the NEO-Personality Inventory (NEO-PI-R), Allik and McCrae (2004) generated a map of personality traits based on self-reports of college-age adults from 36 cultures. They found a separation of European and American cultures from Asian and African cultures, where European and American cultures were higher in extraversion and openness, but lower in agreeableness. Despite these differences, one important observation was that there was typically more variation within a culture than between cultures (Allik and McCrae, 2004).

Though these cultural differences may be attributed to differences in what is socially-desirable in each culture (Allik and McCrae, 2004), there is some evidence that culture impacts personality through other means – specifically, evolved processes that can affect

personality. One mechanism that has been proposed to lead to variation in the expression of personality traits across cultures is the behavioral immune system, which is the degree to which individuals are aware of potential disease-causing pathogens and motivated to avoid them. It has been theorized that sensitivity to, and avoidance of disease-carrying pathogens is predicted by the historical prevalence of disease in a given geographical area. Schaller and Murray (2008) determined that in regions with high historical disease prevalence, there are likely to be lower levels of extraversion. This is believed to reflect the degree to which individuals are avoidant of others who may spread disease. Openness to experience is also lower in regions characterized by historical prevalence of disease, given its relationship with experimentation and the potential for exposure to objects or events that may cause harm (Schaller & Murray, 2008).

Though the Big Five seem to be generally descriptive of personalities across cultures, there is nevertheless some debate about its efficacy in capturing all of the variance in how people think and behave. This criticism stems from the fact that the inventory is translated from English, and therefore relies on personality terms that are developed in English and selected by Westerners (Heine, 2016). One solution is to use approaches that rely on situating personality constructs in what is relevant to the culture. For example, using personality descriptors that come from the languages spoken in the regions of interest allows researchers to describe personality in terms that populations might actually use, rather than imposing a Western framework. Many studies have been conducted in the Philippines using this approach, with inventories developed from analyses of self-reported Filipino personality characteristics, which are then compared to the Big Five (e.g. Church & Katigbak, 1988; Katigbak, Church, & Akamine, 1996). These analyses revealed generally good agreement between the Big Five and the dimensions obtained using this method. However, Filipino personality taxonomies tended to yield one or two more factors that are not captured by the Big Five; for example, social potency, which is related to self-assurance (Katigbak, Church, & Akamine, 1996).

Another prominent use of this method is the Chinese Personality Assessment Inventory (CPAI), which reveals a sixth factor labeled interpersonal relatedness that cannot be explained using any of the Big Five personality traits (Cheung et al., 2001). The implication of this finding is not necessarily that universal personality traits do not exist, but perhaps reflects a "blind spot" in Western tools of analysis, where relatedness is de-emphasized (Cheung et al., 2001).

In fact, there is no clear evidence that the Big Five exist among small-scale indigenous societies (Gurven, von Rueden, Massenkoff, Kaplan, & Lero Vie, 2013). Rather, there seems to be a "big two" that emerges, corresponding to prosociality and industriousness. Studies like these suggest that there are inherent difficulties in applying Western models of personality to cultures that are distinct from the West.

There is much that personality psychology can learn from taking a cross-cultural perspective. Understanding how personality operates within culture is a complex task, requiring consideration of how personality is expressed and understood in non-Western contexts. Furthermore, there is not yet definitive evidence of a universal set of human traits, though the fields of personality and cultural psychology have become progressively more committed to resolving this ambiguity (McCrae & Allik, 2002). Scholarship on the personality in culture consistently shows that the people we are, and how we understand the self, is deeply rooted in our cultural context.

Personality Stability over Time

Grant W. Edmonds[1] and Patrick L. Hill[2]

[1] *Oregon Research Institute*
[2] *Washington University in St. Louis*

The Stability of What?

Personality stability refers to the extent to which a person's characteristic ways of thinking, feeling, and behaving remain consistent and recognizable over time. It can be helpful to think of physical features as an analogue. Consider that you would likely be able to match childhood pictures to present-day pictures of your friends and acquaintances. Even though their faces have changed over time, you can still see that the person in front of you and the child in the picture are the same person. Over longer spans of time, it may become harder to make an accurate match. Currently, our best understanding of personality stability is similar to this. Personality is not perfectly stable. People can and do change as time passes. In most cases though, we can still measure some degree of stability that remains consistent, even over long spans of time.

In order to investigate the stability of personality, it is important to first decide how we are to conceptualize personality. Prior to the widespread adoption of the Big Five model of personality in the mid-1990s, there was no consensus on which constructs to focus on to investigate personality stability. Five broad trait domains, Extraversion, Agreeableness, Conscientiousness, Neuroticism, and Openness/Intellect, have been found to replicate across many different languages, and across different stages of life. By focusing on the Big Five domains, researchers have accumulated sufficient evidence to give estimates of how stable personality is at different points in the lifespan. Research has also addressed how stable personality is over short intervals, over longer intervals, and the rate at which stability declines over ever-increasing periods of time.

Stability can be defined in multiple ways, and research studies focused on "change" or "stability" are complementary. Because of this, all of the ways that personality change is studied can also tell us about stability. Personality stability has been conceptualized in many ways, and could refer to absolute trait levels, the maintenance of a specific

personality profile, the persistence of a personality disorder, or rank-order stability. The two most studied types of stability are absolute or mean-level stability, and rank-order stability.

Mean-level Stability

Mean-level stability refers to the extent of change evidenced in the absolute levels of personality traits across time or ages. If, for example, everyone in a population becomes more agreeable with age, we would observe increases in individual level scores of agreeableness, along with increases in the mean-level across the population. Change of this type can be assessed by either assessing a group of people over time using a longitudinal design, or assessing people of many different ages at one point in time in a cross-sectional design. Interpreting results from both types of studies poses specific challenges. If groups of people born at different times, or cohorts, start with similar mean-levels, then cross-sectional data gives a good picture of mean-level stability across ages. However, cohorts may have different starting points. Longitudinal work can take decades and expensive resources to complete, but has the advantage of directly describing trajectories. Some cohorts may change in specific ways that are unique to their place and time in history. This requires researchers to look at many different longitudinal cohorts. An advantage to using both cross-sectional and longitudinal methods is that we can look for places where these different methods agree. The aggregate picture can point to results that are consistent across cohorts, and methods. Meta-analytic results indicate that mean-levels on the Big Five personality traits are relatively stable, with small mean-level changes occurring at all points in the lifespan for all traits. While some might expect to see the least amount of stability in adolescence, the largest mean-level changes have instead been observed in young adulthood. In general, as people age, they tend to become more agreeable, conscientious, and emotionally stable (Roberts, Walton, & Viechtbauer, 2006). Cumulative changes in mean-levels of these traits over the lifespan can approach one standard deviation in magnitude.

Rank-order Stability

Rank-order stability is assessed by measuring the same sample on at least two different occasions and estimating the correlations between scores on personality dimensions across time. If everyone remains in the same rank with respect to each other on levels of a given trait, the rank-order correlation will be perfect. If many people change standing on a trait relative to each other, the correlation will be reduced in magnitude. Meta-analytic work, which accumulates findings over many studies, indicates that rank-order stability tends to increase with age, reaching a peak sometime after the age of 50 (Roberts & DelVecchio, 2000). Even at the peak of stability, this association is not perfect and thus traits are able to change to some degree.

Because mean-level stability and rank-order stability can be related in complex ways, an accurate description of personality stability must consider both (Edmonds, Jackson, Fayard, & Roberts, 2008). When most people in a cohort or population increase on a trait,

this will be observed as a mean-level increase. This need not affect the rank-ordering within the cohort, in which case rank-order stability and mean-level stability are independent. However, rank-order stability and mean-level changes are not always independent in this way. The best way to address the possible dependency between mean-level and rank-order stability is to investigate both. As an example, research using data from the German Socio-Economic Panel (GSOEP) has allowed for several insights from combining both methods (Lucas & Donnellan, 2011; Specht, Egloff, & Schmukle, 2011). These data comprise large representative samples that span a wide age range, and have now been assessed on the Big Five on more than one occasion. Results using these data show a U-shaped pattern in rank-order stability for most traits with increases across young adulthood, reaching a peak after age 50, followed by declines later in life. In contrast, Conscientiousness showed a different pattern of steady increases in rank-order stability. Mean-levels trajectories differed across traits. Extraversion and Intellect/Openness tended to decline with age, while Agreeableness showed small increases. Conscientiousness increased through most of the lifespan. Neuroticism showed relatively flat mean-level trajectories, with small increases earlier in midlife, followed by declines later in life.

Mechanisms of Stability

Many possible mechanisms have been proposed as drivers of personality stability. Life events that affect personality development may be expected to reduce stability (Allemand, Gomez, & Jackson, 2010). Expectations associated with age-graded social roles have also been proposed as drivers of personality change. One theory of trait stability argues that people select social roles and environments consistent with their personality trait levels. Experiences associated with this selection then reinforce these same traits. This process is referred to as cumulative continuity, or co-responsive development (Roberts & Caspi, 2003). For example, an extroverted person is more likely to choose social rather than solitary situations and select vocations that allow opportunities to be sociable and energetic. This practice can then reinforce the development of this trait, driving stability. In addition, genetic mechanisms play a role in explaining both observed mean-level changes, and patterns of personality stability. Indeed, a comprehensive theory of personality development needs to account for how social-environmental and genetic mechanisms work in tandem to explain change and stability (Bleidorn, Kandler, & Caspi, 2014).

Future Directions

While the current understanding of personality stability rests on large amounts of accumulated data, new results continue to raise interesting questions. For example, recent research using older samples than the age range covered in previous work has shown that in some cases, stability declines in the later stages of life. This decline may result from changes in identity and social roles, age-related declines in cognitive functioning, or declines in general health. Investigating these questions may point to important associations between personality stability and consequential outcomes later in life. Questions remain regarding

the ways rank-order stability declines over long spans of time. As intervals between measurements increase, rank-order stability estimates typically decrease. However, even studies spanning many decades show some amount of rank-order stability in the Big Five (Edmonds, Goldberg, Hampson, & Barckley, 2013). The rate at which stability declines as intervals increase has been theorized to be non-linear, insofar that it approaches a lower asymptote that is greater than zero. In other words, stability may never decline to the point that the correlation across assessments reaches zero (Fraley & Roberts, 2005). Other growing areas of research on stability focus on estimating stability for narrow components or facets of the Big Five, and similarly investigating stability in higher order structures that subsume the Big Five. Observed stability at the Big Five level may result from a causal mechanism operating at these different levels of analysis.

There is much left to learn about the stability of personality over the lifespan. The degree to which we can answer questions about the nature of stability over time depends on having data available where personality is measured on more than one occasion in the same sample, as well as data from cross-sectional samples with wide age ranges. It is also important to consider the interval of measurement, and the point in the lifespan when personality is assessed. By aggregating across many such studies, personality psychologists can answer important questions about the nature of personality stability over time.

Priming

Thomas I. Vaughan-Johnston and Jill A. Jacobson

Queen's University, Canada

Most broadly, priming refers to the activation of mental representations that subsequently affect judgments and/or behavior. Although priming often targets mental representations of goals, attitudes, objects, or stereotypes, it also can be used to temporarily accentuate or suppress personality variables. In this entry, the individual who is exposed to a prime is called a *recipient*, and the construct activated by the prime is called a *target*.

Methods

Researchers have developed diverse methods for priming personality, which are best summarized through two organizing variables: liminality and modality. How the efficacy of priming can be measured also is an important distinction.

Liminality

Subliminal primes consist of stimuli that recipients register but are not consciously aware of (e.g. Weinberger & Westen, 2008). For example, extremely brief (~30 milliseconds) visual stimuli such as images or words will be shown to recipients, presumably activating the associated target in the recipient's semantic network. Subliminality also can be ensured by presenting primed words in recipients' parafoveal visual space (within recipients' sight line but outside of the attentional center known as the fovea). In contrast, supraliminal primes consist of stimuli that recipients are consciously aware of (e.g. reading a passage about empathy); however, they may not be consciously aware of the prime's *effect* on them (e.g. inducing more empathic thinking or behavior). According to Loersch and Payne's (2011) situated inference model of priming, primes often will be effective precisely because recipients are not aware of how a prime has shaped their thinking. That is, recipients typically consider the prime's influence (e.g. the effects on their subsequent thoughts) to be endogenous reflections of their own natural cognition.

Modality

Primes vary widely in their form. The most common form is likely verbal presentations ranging from brief flashes of relevant words (e.g. "RATS" to prime negativity) to lengthy passages designed to direct thinking toward the target. Visual images such as selected individuals' faces have proven effective when those faces are known to the recipient for either personal (e.g. a family member) or general knowledge (e.g. the current president) reasons. However, more behavioral primes also have been used such as having recipients engage in an in-lab competition to prime competitiveness.

Measurement of Priming Effects

A wide variety of dependent variables have been considered in priming research including neuroimaging signals, sentence-completion tasks, ambiguous anagrams, facial expressions, personality questionnaires, subtle measurement of participant behaviors, etc. Zwaan (2013) has argued that on theoretical grounds, one might anticipate smaller effects as one moves along a continuum from internal to external measured outcomes. That is, if priming works by subtly manipulating thought patterns, then larger effects likely will be obtained on cognitive or perceptual outcomes (because these are most directly impacted by a prime), and smaller effects will be obtained on behavioral outcomes (which are only indirectly influenced by the prime). In other words, nodes within a semantic network (one word or concept influencing another) are more proximally related than nodes between semantic and behavioral networks. So, a verbal prime most powerfully will influence a thought pattern but likely will result in only subtle behavioral changes.

Priming of Personality

Researchers prime personality constructs for several purposes. First, because studies of personality characteristics are often correlational, it can be difficult to establish a causal or at least an isolated directional influence of traits on judgments and behavior. For example, Jacobson, Weary, and Lin (2008) conducted several studies on causal uncertainty, the belief that one may not understand causal patterns shaping social events. They found that high causally uncertain people processed social information more when asked to consider the adequacy of their understanding (a sufficiency rule) than if asked to consider whether they were enjoying an information-seeking task (an enjoyment rule), whereas low causally uncertain people did not differ significantly in the two rule conditions. To better establish that this effect was causally driven by causal uncertainty, in Experiment 3, Jacobson et al. primed causal uncertainty by having participants study several sentences known to exemplify causal uncertainty beliefs. When primed in this way, low causally uncertain people responded to the two rules like the high causal uncertainty individuals did in the first two studies. In a similar fashion, cross-cultural researchers have strengthened the link between individual differences in individualism and collectivism as an explanation for group differences between Western and Eastern cultures by priming independent versus interdependent self-construals (Oyserman & Lee, 2008).

In addition, researchers have used priming to establish the contextual nature of personality. For example, Baldwin and Holmes (1987) examined the boundary conditions of individual differences in sexual openness on arousal by having undergraduate women mentally visualize the faces either of their parents or of their campus friends before reading a sexually provocative passage about a woman having a sexual dream. Women who first visualized their parents rated the arousing passage as less enjoyable than did women who had visualized their friends. Thus, they established that the effects of personality differences are susceptible to nudges based on temporarily activated or situational cues.

Moderation of Priming by Personality

Personality factors also can moderate the effects of primes on recipients' judgments and behavior. In several studies, participants' chronic or trait levels on a personality construct have moderated their responses when exposed to temporary activations of that same construct. For instance, in the Jacobson et al. (2008) studies discussed earlier, high causally uncertain people exposed to the causal uncertainty prime no longer responded differently to the two stop rules, a deviation from their usual response pattern caused by priming. Jacobson et al. proposed two explanations for this finding: (1) The chronic and temporary activation of causal uncertainty was additive, making high causally uncertain people so uncertain that they gave up on the task, believing further processing would be futile; or, (2) chronically activated causal uncertainty changed the interpretive context of the prime and made them perceive their temporarily activated causal uncertainty as more extreme. This explanation would fit with previous research (e.g. Herr, 1986) in which people contrast away from primes that are very extreme rather than assimilating their responses toward the primed content. Either interpretation supports an interesting possibility for personality moderation of priming: for people who already possess high levels of a trait, further priming of that trait may diminish or even reverse their typical responses.

Other research has shown that personality can moderate priming more generally. Wheeler and Berger (2007) found that that introverts preferred comfort foods over spicy foods but only after a party prime, which should activate stress in introverts. Extraverts' preferences did not differ across priming conditions. Additionally, people low in self-monitoring (see Self-Monitoring (to include the Self-Monitoring Scale), Assessment of) are more responsive to and show greater behavioral effects of primes than do people high in self-monitoring (DeMarree, Wheeler, & Petty, 2005). These findings support DeMarree et al.'s active-self account of priming, according to which priming works by biasing individuals' self-representations in assimilation to the prime's content. Low self-monitors, who are more likely to use internal cues as the basis for their decisions, also are more susceptible to the internal cue of self-representations activated by a prime.

Criticisms and Responses

Priming research in general has come under fire, particularly for issues relating to replicability (see Replication Research), leading to a heated debate about the legitimacy of priming research. This debate was ignited when Doyen, Klein, Pichon, and Cleeremans (2012)

failed to replicate Bargh, Chen, and Burrows's (1996) research on the effects of priming on elderly participants' walking speed. Some defenders of priming have pointed out that replications actually are quite common when replication-and-expansion studies are considered, many of which investigate personality moderators. For example, in Hull, Slone, Meteyer, and Matthews (2002), an elderly prime did lead to slower walking speeds but only for people high in private self-consciousness (see self-consciousness, Assessment of). Other defenders have argued that primes should not be expected to be invariant across time, situation, and cultures (Cesario & Jonas, 2014). Of course, one concern is that models that predict extreme intercontextual variability become unfalsifiable because non-replications easily can be dismissed as evidence of "hidden moderators." Thus, many researchers now advocate for greater transparency in method and data reporting and for priming researchers to explicitly consider potential moderators of their effects.

Another issue more specific to priming of personality is that the temporary effects induced by primes may be poor substitutes for actual personality traits, undermining the claim that priming personality provides a demonstration of personality traits' causal operations. Personality factors may have longitudinal, downstream effects on cognition, interpersonal relations, and affect that are impossible to simulate through priming. Indeed, primes are unlikely to fully capture all that a personality construct entails. However, the Jacobson et al. (2008) results described earlier as well as comparable results where both dispositional and temporarily primed causal uncertainty show similar effects in reducing stereotyping (Weary, Jacobson, Edwards, & Tobin, 2001) are examples wherein researchers have demonstrated some compelling equivalences between dispositional and primed personality constructs, reaping substantial theoretical gains.

In sum, priming has been a technique to further test and understand the influence of personality on people's judgments and behavior. However, priming research is at a crossroads due to questions of theory and replication. If priming research continues to lose credibility, then personality researchers may lose an important technique for addressing causal influence. Personality researchers may have much to contribute to the priming debate by helping to reconcile some of the conflicting findings by identifying individual difference moderators of priming effects or better understanding the interplay of chronic and temporarily activated constructs.

Realistic Accuracy Model

Tera D. Letzring[1], Douglas E. Colman[2], Sheherezade L. Krzyzaniak[1], and Barbara Wood Roberts[1]

[1] *Idaho State University*
[2] *University of Wisconsin-La Crosse*

The Realistic Accuracy Model (RAM) is a description of the four-step process that describes how accurate judgments are made about the personality traits of others. The model is useful for understanding what has to happen for an accurate judgment to be possible, as well as for identifying moderators of accuracy and ways to increase accuracy. The model was a reaction to the discipline's focus on biases resulting in the misperception of others, and this is the rationale for the explicit focus on accuracy. Furthermore, the model is concerned with judgments of real people based on actual cues that people exhibit, rather than with judgments of hypothetical people based on constructed sentences or descriptions. For this reason, the criterion for determining a judge's level of accuracy is preferably a composite of ratings from the person being judged and others who know this person well.

When discussing this model, and accuracy of personality judgment in general, the term *judge* or *perceiver* refers to the person making the judgments and the term *target* refers to the person being judged. The process of judgment can occur with or without awareness on the part of both the target and the judge. First, targets could attempt to make a certain impression and attend to the cues they give off, and judges could intentionally be attending to targets and attempting to make accurate judgments of their personality. However, targets could also unwittingly emit cues that are relevant to personality and available for others to detect, and judges could pick up on those cues and make judgments without consciously intending to do so.

History

Research on accuracy of personality judgment was first popularized in the decades between 1920 and 1950 by researchers such as Stanley Estes (1938) and Philip Vernon (1933). During this time, research mainly focused on how well personality judgments matched how targets perceived themselves, which is known as *self-other agreement*. However, a methodological

critique by Lee Cronbach (1955) led to a drastic decline of the research in this area. Cronbach argued that there were unaddressed issues in the way accuracy of personality judgment was measured, and these issues could lead to inaccurate conclusions. In particular, he argued that accuracy was made up of several components, not all of which reflected accuracy of the judgment per se. Rather than find ways to assess each component, most researchers shifted their focus to the *process* of personality judgment through the use of hypothetical targets. As a result, the concept of accuracy was largely ignored over the next 20 years.

Around the same time, social psychologists began to focus on the "error paradigm," which asserted that people use representative heuristics, or characteristic ideas about a situation or outcome, to make judgments. This led to the idea that people are actually much more inaccurate in their judgments about others, and further fueled the arguments against studying accuracy. Additionally, attributing behavior to personality, instead of to the situation, was conceptualized as an error that would lead to inaccurate perceptions of others. This error was labeled the *fundamental attribution error* (FAE) by Lee Ross in 1977. Research on the FAE was popular for many decades, and further isolated accuracy research.

In the early 1980s, researchers such as David Funder (1982) and William Swann (1984) began to challenge the widely-held concepts of inaccuracy and the fundamental attribution error, and instead argued that people are surprisingly *accurate* in their judgments of others. Accuracy research made a return, but the important question of what criteria would be used to measure accuracy still remained. Different approaches developed in answer to this question. The Realistic Accuracy Model (RAM), proposed by David Funder in 1995, is one such approach that focuses on how accurate judgments are made. RAM draws inspiration from Egon Brunswik's Lens Model (1956), which represents the relationship between an object/person and an accurate judgment of that object/person. According to this model, objects give informational cues from which judgments can be inferred. These cues vary in their validity, in terms of how relevant they are to the attribute being judged. In the second stage of the model, a judge utilizes the cues. Accuracy will be highest when a judge utilizes cues with high validity and does not utilize cues with low validity. RAM expands upon this model, and identifies four stages of the judgment process.

Stages of the Realistic Accuracy Model

According to the model, the four stages must occur in a specified order to result in accurate judgment: *relevance*, *availability*, *detection*, and *utilization*. These stages are conceptualized to be multiplicative, meaning that in order for accuracy to be perfect, all stages must be perfectly completed. Imperfect completion of any one stage will result in decreased accuracy. Furthermore, failure at any one stage will render accurate judgments impossible.

Relevance

The first stage is relevance, which speaks to the quality of the information emitted by the target. In other words, information is highly relevant if it is related to the trait being judged. For example, timid behavior is relevant to shyness. Further, cues will be more relevant when the target is behaving in a genuine manner and not trying to create a false or misleading impression. Cues are also likely to be more relevant to personality when

situational demands are weak to moderate, which means that people have more flexibility in terms of their behavioral choices; whereas cues are less likely to be relevant to personality in strong situations in which behavior is constrained and therefore less likely to be related to personality.

Availability

The second stage is availability. A cue is available when it can be detected by a judge. Available cues are found in both verbal and nonverbal overt behavior. A thought or emotion is likely to be relevant to personality, but unless that thought or emotion is expressed in a manner that makes it available to a judge, it will not facilitate accurate judgment. Therefore, targets play a major role in a cue's availability by being expressive and acting in a way that is consistent with their personality. There is also a situational aspect to availability because some situations will elicit cues to some traits and not others. For example, cues to sociability are more likely to be available at a social gathering, whereas cues to work ethic are more likely to be available in a work setting. Another situational factor that can influence the availability stage is the behavior and characteristics of the people with whom the target is interacting. If the interaction partners are able to create a situation in which targets feel comfortable to express their true nature, then more relevant cues are likely to be available.

Detection

The third stage is detection, during which the judge becomes aware of the relevant and available cues produced by the target. Accuracy will be lower when the judge fails to pick up on the cues emitted by the target, which could result from not being in the same physical location as the target, or from being distracted or disinterested when in the same physical location. Conversely, accuracy will be higher when the judge is in the same situation as the target and pays attention to the target.

Utilization

The fourth and final stage is utilization, during which the judge correctly uses the relevant cues that were detected to make an accurate personality judgment. Accuracy of judgments of the same targets based on the same cues will vary if judges use the information differently to arrive at a judgment. Furthermore, each personality trait has multiple relevant cues, so judges must correctly combine these multiple cues in order to make accurate judgments.

Moderators of Accuracy

An explicit consideration in the development of RAM was the ability to theoretically account for variables that make accuracy more or less likely. Such variables can be organized into four categories: aspects of the judge, characteristics of the target, features of the trait, and properties of the information on which judgments are based. David Funder (1993, 1995) identified these four moderators of accuracy as the *good judge*, *good target*, *good trait*,

and *good information*. *Good* precedes each of the moderators to highlight the focus on the factors that make accurate judgments *more* likely.

Good Judge

The idea that individual differences exist in the ability to accurately judge others is the foundation of the *good judge* moderator. This moderator is primarily a consequence of the utilization and detection stages of RAM. However, aspects of the judge could also prompt targets to divulge more relevant information, which would affect the relevance and availability stages. Investigating this notion, Tera Letzring (2008) found that several characteristics and behaviors of judges were related to accuracy of personality judgment. For instance, being agreeable and having "purpose in life" were positively related to accuracy. Behaviorally, the use of basic social skills (e.g. eye contact, expressing warmth), enjoyment of the interaction, and liking of the target, among other aspects, were positively related to accuracy. Alternatively, yet intuitively, needing reassurance, undermining, and seeking advice were negatively related to accuracy. It was concluded that such a pattern of results supports the idea that good judges elicit more cues from the target that can then be used when making judgments. Given this, one would expect that others in the multi-person interaction or even observing the interaction should also have that information available to them for making more accurate judgments. Indeed, when judges made ratings based on observing recorded interactions, there was a positive relationship between the number of partners for a target who were good judges and the accuracy with which that target was judged.

Good Target

Much like the good judge, individual differences in how accurately targets are judged, which is known as *judgability*, have been found by several researches, including C. Randall Colvin (1993), Lauren Human, and Jeremy Biesanz (2013). From a theoretical perspective, the *good target* moderator is a product of the availability and relevance of information because people who make more relevant cues available for others to detect are easier to accurately judge. According to Daryl Bem and Andrea Allen (1974), individuals who behave consistently across situations and over time are more likely to be judged accurately because this allows for relevant cues to be available to judges on an ongoing basis. Similarly, targets who are behaviorally active emit more information that can be detected, thus providing more relevant cues to judges and thereby increasing how accurately they are judged. Judgable individuals are often described as warm, cheerful, and dependable; whereas less judgable individuals are described as hostile, deceitful, and moody. Moreover, people with high social status, good psychological adjustment, and high levels of socialization are likely to be good targets.

Good Trait

The third moderator, *good trait*, refers to the notion that some traits or characteristics tend to be more accurately judged than others. This moderator is related to the relevance and

availability stages of RAM. Traits associated with many cues that are highly visible and frequently available are more accurately judged than traits associated with cues that are less visible and less likely to be available. This aspect of the good trait has been referred to as visibility or observability. For instance, the trait of extraversion is related to behaviors such as talking in a loud voice, moving quickly, and behaving boldly – all of which are highly available – and therefore extraversion is a good trait. On the other hand, the trait of neuroticism is related to how people interpret situations and feelings of anxiety and other negative emotions – which are often not highly available – and therefore neuroticism is not a good trait. However, the ease with which a trait is judged can depend on who is making the judgment, especially in terms of whether judgments are made about the self or another person. Although neuroticism is difficult to judge in another person, the thoughts and feelings related to neuroticism are available to the self and therefore this trait is more accurately judged by the self than by others. Conversely, traits such as extraversion are commonly judged from overt behaviors, which are more salient to another person, thus allowing for more accurate judgments by others than by the self.

Another aspect of traits that is related to accuracy is the level of evaluativeness, or favorability. Oliver John and Richard Robins (1993) found that when judging the self as compared to judging others, people are more likely to be affected by a self-enhancement bias. Indeed, discrepancies have been found between self-ratings and ratings by others on highly evaluative traits.

Good Information

The *good information* moderator of accuracy posits that aspects of the information emitted by the target influences accuracy of judgments. One aspect of good information is *quantity*, or the amount of information that is available to the judge. Strong evidence has been found by several researchers to support the existence of the *acquaintanceship effect*, or the increase in accuracy that is associated with knowing a person for longer and thereby having access to more information about that person. However, C. Randall Colvin and David Funder (1991) identified a boundary on the acquaintanceship effect such that acquaintances and strangers are equally good at predicting behavior when strangers have previously observed the targets in a similar situation.

A second aspect of good information is *quality*, which reflects how relevant the information is to the characteristic being judged. In line with this theoretical view, research by Tera Letzring, Shannon Wells, and David Funder (2006) has shown that higher quality information is positively related to accuracy of judgments, when information quantity is held constant. Furthermore, Tera Letzring and Lauren Human (2014) found that dyads who discussed their behaviors or thoughts and feelings obtained higher levels of accuracy about how people are unique than did dyads that engaged in activities together. Interestingly, there is also evidence that accuracy of judging different traits is related to disclosing different types of information. Specifically, Andrew Beer and Cody Brooks (2011) found that information about values is related to greater accuracy in judgments of neuroticism, whereas factual information is related to greater accuracy in judgments of conscientiousness.

Implications of the Realistic Accuracy Model

There are three important implications of RAM. The first is that making an accurate judgment is difficult because all four stages of the judgment process have to be successfully completed in order for accuracy to be possible. This means there are four stages at which things can go wrong. The second implication is that moderators of accuracy must affect one or more of the stages. The good judge has traditionally been thought to affect the detection and utilization stages, but there is now evidence that judges can also affect the relevance and availability stages; the good target and good trait are related to the relevance and availability stages; information quantity is related to the availability stage and information quality is related to the relevance stage. The third implication is that accuracy can be improved by increasing the level of success at one or more of the stages of RAM. Therefore, accuracy can be increased by making cues more relevant, increasing the availability of cues, increasing how many relevant cues are detected, and helping judges better utilize cues.

Current Emphases

The current emphasis on research related to RAM is on deepening the understanding of the moderators of accuracy. One interesting aspect of this emphasis is the consideration that accuracy may differ as a function of the relationship between the judge and target and of the trait being judged. The Self-Other Knowledge Asymmetry model was proposed by Simine Vazire in 2010 to describe this difference, and reflects the finding that accuracy differs depending on whether judgments are about the self or another person. Judgments about the self tend to be more accurate for less visible traits, and judgments about others tend to be more accurate for more evaluative traits.

Another current emphasis is on understanding different components of accuracy, and how these components relate to the moderators of accuracy and other important outcomes. It has long been known that accuracy scores include several important components, but more standardized approaches to decomposing accuracy into these components have only recently emerged. In 2008, R. Michael Furr described how to use a profile similarity approach to examine the components of normativeness and distinctiveness. Profile similarity reflects the similarity between (1) how several characteristics are rated by the judge and (2) an accuracy criterion for those same characteristics (which can be composed of self-ratings, a composite of ratings from people who know the target well, and/or behavioral indicators of the characteristics). Normativeness is the level of similarity between an individual set of ratings and an average set of ratings based on a large group of people. Distinctiveness is the level of similarity between the unique elements of two sets of ratings, typically in terms of how the ratings differ from the average set of ratings. In 2010, Jeremy Biesanz proposed a multilevel modeling approach for estimating these two components of accuracy, in which the normative/average and distinctive ratings are simultaneously used to predict the judges' ratings. Analyses that

take these components of accuracy into account are illuminating ways that the components are differentially influenced by factors that include whether the judge is motivated to be accurate, the type of information that is available to the judge, and how accuracy relates to important outcomes such as perceptions of interpersonal support and life satisfaction of the judges.

Future Directions: Extensions and Applications

The Realistic Accuracy Model has primarily been applied to judgments of personality traits, in particular to characteristics contained in the 100-item California Adult Q-set, and to the traits contained in the Big Five taxonomy (i.e. extraversion, agreeableness, conscientiousness, neuroticism, and openness to experience). Researchers are beginning to extend the model to judgments of other constructs, including personal values and moral character, risk-taking, and emotions. The model could be further extended to apply to judgments of empathy and perspective-taking. Such an extension would allow researchers to examine levels of accuracy for constructs other than personality traits and would generate important information about the generalizability of previous findings for additional constructs. Furthermore, all of these constructs could be examined in both children and older adults, as the existing research has been conducted mainly on college students and young adults.

Research on meta-accuracy, or how accurate people are about how others see them, could also incorporate the process and moderators of RAM. Research by Erika Carlson and R. Michael Furr (2013) has examined how meta-accuracy relates to information quantity and quality, but explicitly examining meta-accuracy within a RAM framework is likely to lead to new research questions and insights. For example, research could explore whether the moderators work in the same ways for meta-accuracy as they do for accuracy, and the extent to which the process of making an accurate judgment generalizes to making an accurate meta-judgment.

Some research has started to examine the consequences of accuracy as they relate to good judges and good targets, with a consistent finding that the ability to both judge and be judged accurately is related to several beneficial outcomes. For example, judging strangers as similar to the average is related to agreeableness, life satisfaction, positive affect, interpersonal control, and interpersonal support; whereas being a good target is related to psychological adjustment and social status. Additional research is needed to examine how these moderators relate to other important variables and to examine the direction of a causal link between the moderators and these variables.

A final future direction is to begin to examine how the moderators interact with each other to influence levels of accuracy. Some work exists in this area, primarily in terms of the interaction between the good trait and good (quality) information moderators. Additional questions such as the following could be addressed: Are judges with certain characteristics especially well-suited to detect cues to certain traits? What types of characteristics benefit the most from increased information quantity?

Rejection Sensitivity

Gili Freedman

St. Mary's College of Maryland

Rejection Sensitivity Defined

Rejection sensitivity is a cognitive-affective individual difference such that individuals with higher levels of rejection sensitivity are more likely to worry about rejection occurring, perceive ambiguous situations as involving rejection, and react negatively to instances of rejection (Feldman & Downey, 1994). A rejection sensitive individual will view relationships from the lens of a working model in which rejection is a constant threat and something to be strongly avoided.

Explanations of Rejection Sensitivity

The concept of rejection sensitivity stems from Attachment Theory and Social Cognitive theory. According to Attachment Theory, children form working models of how relationships function from their relationship with their parents. Rejection sensitivity was first described in research on childhood exposure to family violence and its later impact on adult relationships. Research on rejection sensitivity and attachment has shown that individuals with higher levels of rejection sensitivity are more likely to be insecurely attached. That is, individuals with anxious-avoidant or anxious-ambivalent attachment styles are more likely to score higher on rejection sensitivity than individuals with secure attachment (Feldman & Downey, 1994).

In addition to Attachment Theory, Rejection Sensitivity derives from work on Social Cognitive Theory. Social Cognitive Theory describes the components of working models: encoding, expectancies, values, and strategies. In other words, Social Cognitive Theory explains how individuals make sense of and react to their social worlds. Specifically, individuals with higher levels of rejection sensitivity interpret the world in a way that matches their prior experiences with rejections in relationships, which then reinforces their rejection sensitivity toward future experiences (Feldman & Downey, 1994).

Measurement of Rejection Sensitivity

Rejection sensitivity is most commonly measured using the Rejection Sensitivity Questionnaire (RSQ; Feldman & Downey, 1994). This questionnaire provides participants with 18 ambiguous social situations in which rejection could occur. For example, one situation describes asking a parent to come to a special occasion (Feldman & Downey, 1994). For each social situation, participants are asked two questions. First, they are asked how concerned or anxious they would be that the character in the situation would reject them. Second, they are asked how likely the character would be to accept them (or the request they made). Researchers calculate the rejection sensitivity score by reverse-scoring the likelihood items and multiplying them by the expectancy items. Thus, the rejection sensitivity scores reflect anxiously expecting rejection across a set of social situations.

Impacts of Rejection Sensitivity

Rejection sensitivity has a range of associated impacts in both romantic and non-romantic contexts. In romantic contexts, a higher level of rejection sensitivity in one romantic partner is associated with less satisfaction in the relationship for both partners. In fact, rejection sensitivity can be seen as a self-fulfilling prophecy such that expecting rejection seems to elicit it. Specifically, following conflict, partners of rejection sensitive women become more withdrawn and critical, which leads to lowered relationship satisfaction for both partners. In addition, rejection sensitive women are more negative during conflict, and their partners are angrier after conflict (Downey, Freitas, Michaelis, & Khouri, 1998). Thus, a rejection sensitive partner can be caught in a cycle of expecting rejection and therefore receiving more rejection. Furthermore, couples with a rejection sensitive member are more likely to break up than couples without a rejection sensitive member (Downey, Freitas, et al., 1998).

The influence of rejection sensitivity on relationship outcomes is often associated with distinct gender differences. For example, rejection sensitive romantic partners who are male are seen as hostile, whereas rejection sensitive romantic partners who are female are seen as jealous by their romantic partners (Downey & Feldman, 1996). In addition, women high in rejection sensitivity are more likely to engage in self-silencing (i.e. not voicing one's opinion if it would contradict a partner's opinion) to accommodate a romantic partner and feel greater hostility following rejection by the partner (Romero-Canyas, Reddy, Rodriguez, & Downey, 2013).

Rejection sensitivity is also related to aggression and violence. First, rejection sensitivity mediates the relationship between childhood exposure to family violence and having insecure adult attachment (Feldman & Downey, 1994). Second, having higher levels of rejection sensitivity is associated with engaging in aggressive and violent behavior. For example, men high in rejection sensitivity who are strongly invested in having a romantic relationship are more likely to report engaging in dating violence (Downey, Feldman, & Ayduk, 2000). Furthermore, rejection sensitivity mediates the relationship between experiencing rejection and engaging in aggressive behavior toward a stranger (Ayduk, Gyurak, & Luerssen, 2008). Rejection sensitivity is also implicated in aggressive behavior in children. Specifically, rejection sensitivity predicts how children will feel in a situation involving an

ambiguous social rejection and is associated with more aggressive behavior toward peers in school. Children who angrily expect rejection feel more distressed than children without those angry expectations when they are told that a friend did not want to do an activity with them. Furthermore, children with angry expectations of rejection show lowered academic performance throughout the year and engage in more antisocial behavior than children without angry expectations of rejection (Downey, Lebolt, Rincón, Rincón, & Freitas, 1998).

Forms of Rejection Sensitivity

Rejection sensitivity has been used as an individual differences construct in both children and adults. The foundational research on rejection sensitivity examined the influence of it on adults (Downey & Feldman, 1996), but later examinations extended to include children. A children's rejection sensitivity questionnaire has been created with child-appropriate rejection situations (Downey, Lebolt, et al., 1998). As with the adult-version, the children's rejection sensitivity questionnaire asks participants about how they would feel if the character in the situation rejected them and how likely rejection is to happen (Downey, Lebolt, et al., 1998). Rejection sensitivity can also occur in older adults when they anxiously expect rejection due to their age: this is termed age-based rejection sensitivity. This form of rejection sensitivity is positively associated with loneliness and depression and negatively associated with life satisfaction, social functioning, and physical health (Chow, Au, & Chiu, 2007). In other words, individuals with higher levels of age-based rejection sensitivity show poorer mental and physical health.

Two other status-based forms of rejection sensitivity are gender rejection sensitivity and race rejection sensitivity. Gender rejection sensitivity is when individuals anxiously expect rejection due to their gender (e.g. a woman expecting not to be called on in a physics class because of biases toward women). Gender rejection sensitivity predicts feeling alienated, reduced motivation, self-doubt, and less willingness to meet with an unwelcoming professor. Gender rejection sensitivity also predicts engaging in academic self-silencing, or not voicing oneself in academic settings to avoid conflict and rejection (London, Downey, Romero-Canyas, Rattan, & Tyson, 2012). Finally, race-based rejection sensitivity, or anxiously expecting rejection due to one's race (e.g. an African American man expecting an interview to go poorly because of biases toward African Americans), is associated with lower well-being, less belongingness, and feeling less positive toward peers and professors (Mendoza-Denton, Downey, Purdie, Davis, & Pietrzak, 2002). Each of the forms of rejection sensitivity has its own questionnaire, all of which use the same format as the Rejection Sensitivity Questionnaire. That is, there are multiple social scenarios and participants indicate their anxious expectations and estimates of the likelihood of rejection.

Similarities of Rejection Sensitivity to Other Constructs

Although rejection sensitivity shares similarities with other individual differences related to interpersonal functioning, it is a distinct construct. For example, social anxiety (see Social Anxiety and Social Anxiety Disorder), self-esteem (see Self-esteem, Theory of), neuroticism

(see Neuroticism), and extraversion (see Extraversion) are all related to rejection sensitivity. That is, individuals who are more rejection sensitive are likely to have higher levels of social anxiety and neuroticism and lower levels of self-esteem and extraversion. However, rejection sensitivity is better able to predict how individuals expect and interpret social rejection (Downey & Feldman, 1996), and the relationship between rejection sensitivity and rejection-related outcomes is not dependent on the above mentioned constructs.

Resilience Theory of, Not Just the Trait Dimension

Anthony D. Ong and Celine Cammarata

Cornell University

Definition and Approaches to Studying Resilience

Resilience has numerous meanings in prior research, but generally refers to a process reflecting relatively *positive adaptation* in the context of significant *risk* or adversity. Underlying this broad definition are two specific conditions: exposure to significant risks and evidence of maintenance or recovery of adaptive functioning despite serious threats to development. Historically, resilience research has been largely the purview of developmental investigators dealing with early childhood and adolescence. In early investigations of childhood resilience (e.g. Garmezy, 1985; Rutter, 1987), risk factors were defined as discrete experiences that carried high odds for maladjustment, such as parental psychopathology or community violence. In later work (e.g. Luthar & Cushing, 1999; Masten & Wright, 1998), the concept of risk was broadened to include cumulative risk indices or tallies of adverse life events over time; acute trauma and chronic life difficulties, such as sexual abuse or neighborhood disorganization; and factors that statistically predicted later maladjustment in the general population (e.g. low birth weight).

Positive adaptation, the second core component of resilience, represents adaptation that is substantially better than would be expected given exposure to significant risk. Although indicators of positive adaptation have varied across the context, population, and risk factor under study, extant conceptualizations have generally included competence under challenge. Among young children, for example, competence has been defined in terms of the development of a secure attachment with primary caregivers, and among older children, in terms good academic performance and positive relationships with peers (Luthar, Cicchetti, & Becker, 2000). A central objective of resilience researchers is to identify *protective factors* that served to ameliorate the adverse effects of risks. On the basis of early reviews of the childhood and adolescence literature, Garmezy (1985) described three major categories of protective factors: *individual attributes*, such as an engaging "easy" temperament or good self-regulation skills; *relationships*, including those with parents and teachers that are high in warmth and support on the one hand, and appropriate

control or discipline on the other; and *external support systems*, such neighborhoods that are high in levels of cohesion and community belonging. These protective factors have been reliable in predicting positive psychological functioning following adversity.

At the other end of the life course is the growing literature on *optimal aging* (Baltes & Baltes, 1990; Rowe & Kahn, 1987) that has delineated distinct changes in adaptive capacity across multiple life domains. This work underscores distinctions between resilience as *recovery* from the negative consequences of adversity, and resilience as *maintenance* of relatively stable, health levels of psychological and physical functioning in the face of cumulative risks (Ong, Bergeman, Bisconti, & Wallace, 2006). Other research has conceptualized resilience as distinct from the process of recovery (Bonanno, 2004). This perspective derives from studies demonstrating that resilience and recovery are distinct outcome trajectories that are empirically separable following highly aversive events such as interpersonal loss and psychological trauma. Finally, several lines of adulthood research emphasize the need to assess positive outcomes such as psychological well-being and growth in response to challenge (Ryff, Singer, Love, & Essex, 1998). Studies within this tradition have elaborated how numerous life course factors – including age-graded influences (e.g. caregiving), normative transitions (e.g. bereavement), nonnormative events (e.g. military deployment), and chronic life difficulties (e.g. economic disadvantage) – are linked to various aspects of adult mental and physical health.

Methodological Challenges and Future Directions

Both theoretical and empirical work suggest that comprehensive understanding of resilience requires a broad integrative framework that addresses the need for (1) reliable and theory-driven measures of positive health and well-being, (2) study designs that link information at different levels of analysis, (3) methodological approaches that facilitate characterizations of life histories of resilience in the face of adversity, and (4) intervention strategies that foster resilience.

Defining and Measuring Well-Being

In the resilience literature, most researchers agree that it is important to consider adaptive functioning more broadly beyond just the avoidance of psychopathology or negative developmental outcomes. A growing research interest seeks to delineate the specific components of well-being that are central to resilience as the capacity to thrive and flourish, and not just avoid illness and maladjustment. This research integrates multiple dimensions of *hedonic* (i.e. life satisfaction, affect balance) and *eudaimonic* (i.e. self-acceptance, personal growth, purpose in life, positive relations with others, environmental mastery, and autonomy) or evaluative well-being.

Linking Resilience to Biology and Neuroscience

Both child and adult literatures emphasize the need to bring physical health into the conception of resilience, thereby underscoring a joint emphasis on the mind and the body in understanding positive adaptation to stress. A key task of this approach is to identify the

biological processes underlying the capacity to thrive, flourish, and be well, particularly in the face of adversity. The central questions of this research are two-fold: First, what are the biological underpinnings of resilience? Second, is resilience at the biological level fostered by specific affordances in the social and emotional environment? Currently, little is known about the circumstances of life – the combined impact of major, chronic, and daily stressors – that may leave the brain vulnerable to future psychopathology.

Results of human and animal studies clearly establish that resilience connotes substantial differences in neurotransmitter systems, endocrine systems, synaptic plasticity and circuits, and even the electrical properties of individual neurons (Russo, Murrough, Han, Charney, & Nestler, 2012). Elucidating the neural mechanisms that directly drive positive or negative adaptation across different risks conditions provides a framework for understanding the role of genetic contributions to vulnerability and a protective mechanisms that ultimately may allow researchers to target therapeutic interventions to strengthen particular brain systems implicated in resilience (Caspi & Moffitt, 2006; Greenberg, 2006). This area of investigation is actively developing, and a growing number of functional magnetic resonance imaging studies are specifically probing resilience, revealing both structural and dynamic neural substrates of positive adaptation (Van der Werff, van den Berg, Pannekoek, Elzinga, & van der Wee, 2013).

Resilience as Life History

Central to understanding resilience is compiling *life history* data, where the objective is to work in the middle ground between traditional *idiographic* and *nomothetic* approaches. This work has been guided by the overarching question of what turning points define well-being and hone resilience A guiding principle of this work emphasizes the in-depth investigation of core themes in individuals' lives, how such themes are grounded in social, cultural, historical, and familial contexts, and the extent to which events and behaviors in context shape the varying life-history pathways through adversity and to resilience. The qualitative aspect of this research affords a more nuanced understanding of how diverse events and experiences across multiple life domains influence life history, and how such histories are linked with later resilience.

Fostering Resilience

In view of accumulated evidence, there is a need for effective interventions that target not just children and adults, but also their families and communities. Among leading candidates for fostering resilience are the role of family supports (e.g. nurturing intergenerational ties) and neighborhood resources (e.g. coalitions, faith-based organizations). Likewise, emergent infrastructures (e.g. the built and natural environment, social capital, civil governance) that foster and sustain a coherent sense of community, while also aiding in recovery from crisis and disaster may contribute to community resilience (Cacioppo, Reis, & Zautra, 2011). It is critical, however, that future studies examine the extent to which these factors are salient in the specific risk condition examined (Luthar et al., 2000). Detailed analyses of these and other variables will deepen our understanding of the resilience process.

Schemas, Theory of

Shana M. Needham and Jill A. Jacobson

Queen's University, Canada

A schema is a cognitive structure that helps organize existing and new knowledge. Schemata, or now more popularly referred to in the plural as schemas, adapt to time and context to make meaning out of new events by referencing previously acquired knowledge. The integration of knowledge into pre-existing cognitive structures helps simplify one's world by making expectations clearer and predictions easier. Through this process of integration, the links to different concepts begin to expand, resulting in more complex networks of related ideas. For example, individuals understand themselves because they have knowledge of themselves across different contexts, but this knowledge also is influenced by their schemas of relationships. Given that schemas play such an intricate and important role in how individuals make meaning of their environment and experiences, the topic has produced several extensive lines of research.

Immanuel Kant was perhaps the first to introduce this construct when he described transcendental schemas in the *Critique of Pure Reason*. Kant argued that the mind has a template that links abstract thoughts to more concrete ideas. More importantly, Kant argued that these processes are an attempt to logically make meaning within time and context based on intuitions. This conceptualization laid the foundation for early psychological research on schemas, which began in the early twentieth century with work by gestalt and cognitive psychologists.

Gestalt psychologists took an interest in schemas because they wanted to better understand how people perceive their environment, stressing that the relationship between single perceptions and the larger cognitive processes. In his 1932 book, *Remembering: A Study in Experimental and Social Psychology*, Frederic Bartlett (1932) published the first psychological work to use the term schema. His goal was to outline empirically the processes proposed by Kant in regards to memory and cognitive processes. He suggested that previous knowledge helps to filter and organize acquired information and make sense of it, a process that occurs so frequently these networks are constantly changing.

Bartlett's outline of how schemas evolve led to an extensive line of research regarding learning and development. In his 1952 book, *The Origins of Intelligence in Children*, Jean

Piaget argued that people either assimilate information into existing schemas because it is consistent with previous experiences, or they alter their schemas because of an inconsistency between the past and present information. Piaget's application of schematic theory focused on sensory motor development in the first years of life, and Schmidt (1975) later expanded upon this work by using the theoretical framework of schemas to provide a strong empirical argument against loop-theory, a comparator model of learning from the behaviorist tradition. Schmidt's work helped to generate a competing theoretical perspective based on cognitive processes that continues to be pursued and supported today.

Bartlett also proposed a role for social interactions in schemas, specifically that others influence the information that is being processed and how it is processed. Kuethe (1964) argued that social interactions provide rewards to individuals by providing them with information that then can be applied to future social interactions. For example, one's understanding of romantic partners is based on witnessing romantic interactions (e.g. between parents, grandparents, friends) or experiencing interactions with one's own romantic partners (e.g. arguing with one's spouse).

Self-schemas

The importance of individual characteristics on the development, interpretation, and use of schemas is no more influential than when it is applied to the self. Markus (1977) contends that a vast majority of information individuals process is relevant to the self. The primary purpose of self-schemas is to provide consistency in how individuals process cognitive information about themselves. Although self-schemas are an important component of maintaining a consistent self-concept, these schemas are just as complex as any of the aforementioned schemas. Indeed, the self-schema are a major component of personality. Markus suggested that if individuals have a developed self-schema, they then: (1) are able to easily process information about themselves within a given domain, (2) can support this information with behavioral references from that domain, (3) can predict behavior within that domain in the future, and (4) are able to resist contradictory information about themselves.

Markus (1977) examined the influence of self-schemas in greater detail by categorizing individuals as schematics vs. aschematics based on their responses to scale items about a particular dimension as well as the importance of that dimension to their self-description. Schematics rate themselves very high or low on a series of related adjectives or semantic differentials and also rate these traits as high in importance. Aschematics do not endorse either pole (i.e. they score closer to the midpoint) and rate the traits as low in importance. Markus found that schematics – specifically in her study, people who were labeled as being schematic for independence or dependence – self-categorized more quickly, had more elaborate behavioral descriptions in line with their self-schemas, and predicted future behaviors in line with their self-schemas would be more likely than did aschematics who tended not to significantly differentiate between independence and dependence in their response latencies, descriptions, and predictions.

Given the implications of schemas for personality, several clinical frameworks have been developed in an attempt to resolve issues that occur when self-schemas go awry. The two most prominent theories that examine the influence of schemas in a cognitive setting are Beck's schema theory and Young's schema therapy. Both of these theories propose that

clinical issues are due to the development of self-schemas. According to Aaron T. Beck (see Aaron Beck), negativity becomes ingrained in the cognitive structure of a schema that then becomes either hypervalent or inactive depending on the situation in which the schema is activated. Furthermore, Beck argued that the content of the schemas is what contributes to the symptoms of the disorder (e.g. depressive schemas consist of negative events or information).

Similarly, according to Young's schema therapy, schemas play an important role in psychological disorders, so targeting schema can be an effective form of treatment. The purpose of the therapy treatment is to evaluate the developmental trajectories of schemas by focusing on the importance of interpersonal relationships and how to stop the negative patterns they produce (Young, Klosko, & Weishaar, 2003). In assessing this recently developed therapy, de Klerk, Abma, Bamelis, and Arntz (2017) found that both patients and therapists evaluated the benefits of schema therapy positively, but many believed that the length of the therapy was too fast paced to accomplish all of its goals.

Individual Differences

Personal characteristics are not only affected by but also in turn influence schema construction and use. For example, in Carlson and Price (1966), participants categorized human silhouettes and geometric forms. The findings supported Kuethe's argument for general organizational patterns of classification in social schemas, but personal characteristics (e.g. perceivers' age, gender, and the interaction between age and gender) also influenced people's organization of the categories. More specifically, older age was associated with more concrete categorizations, men were more likely to categorize children and mothers closer together than women did, and older men were more likely to make vertical categorizations than younger men.

Furthermore, individual differences also influence how people develop and use self-schemas. Swann (1983) argued that prior social experiences help individuals formulate an understanding of themselves as others see them and integrate that understanding into their self-identity. Consequently, self-schema affect people's choices of whom to interact with and how they communicate with those individuals. In an effort to maintain consistency about the self, individuals behave in a way that produces feedback consistent with their self-schema. For example, if an individual wants to be perceived as professional, then he or she will wear business attire in the hopes of being complimented or recognized for being professional.

Although the evidence that self-schemas influence the way that individuals interact with others is consistent, the evidence about how self-schemas influence the interpretation of others is mixed. Fong and Markus (1982) found that self-schemas influenced the types of information that individuals tried to gather about a target. For example, individuals who rated themselves as extraverted were more likely to select extravert-oriented questions for a target. Consistent with these findings, Green and Sedikides (2001) found that behavior predictions about a target varied based on the perceivers' self-schema. However, their findings suggest the use of self-schemas in these predictions was the result of ambiguity in a target's personality. For instance, when personality traits were more apparent, such as morality, people relied less on their self-schemas to understand the target.

Conclusions and Future Directions

In sum, schemas serve a variety of important functions that allow people to understand not only themselves and others but also the effects of time and context. Early research merely attempted to address how the cognitive processes associated with schema construction help individuals make meaning. Later researchers focused on development and learning processes to understand how new and old information are integrated. Current research is focused more on self-presentation in the digital world (e.g. Ahadzadeh, Sharif, & Ong, 2017) and how relational schemas influence romantic relationships (e.g. Lemay & Razzak, 2016). Nevertheless, research is still attempting to ascertain just how much impact schemas may have on various psychological outcomes. One large unanswered question is: Can you examine a single schema in isolation, and if so, what are the practical implications of this research?

Self-Determination Theory

Frank Martela

Aalto University

Self-determination theory (SDT) is an empirically based, organismic theory of human nature and behavior that focuses especially on motivation, growth, personality development and wellness (Ryan & Deci, 2017). It is rooted in the assumption that humans are inherently curious, self-motivated and growth-oriented beings that are not only reactively responding to environmental stimuli but actively self-regulate their lives toward growth and integrity following their internal motives, goals, and values. At the same time the theory acknowledges that human vitality and self-motivation can be significantly diminished in certain contexts and following certain conditions of upbringing. Accordingly, the theory is especially interested in identifying the environmental and social conditions in families, classrooms, workplaces, and other life domains that foster or undermine individual's self-motivation, vitality, and wellness. In other words, the theory aims to identify what conditions and contexts most consistently lead to human flourishing.

The work toward the theory started in early 1970s when Edward L. Deci demonstrated in a number of experiments that externally rewarding certain behavior could undermine people's intrinsic motivation to engage in such behavior when rewards were absent (e.g. Deci, 1971). This was in stark contrast to the behaviorist assumptions dominant at that time according to which human behavior is to a large degree determined by external reinforcers. Nevertheless, the empirical evidence for the role of intrinsic motivation in explaining human behavior started to accumulate, and in the 1980s Deci – together with Richard M. Ryan, the second founding father of the theory – formalized the theory, and extended it beyond intrinsic motivation to a general theory of motivation and wellness (Deci & Ryan, 1985a). Since the early work by Deci and Ryan, they have been joined by a growing number of researchers that have expanded the theory and taken it from personality and social psychology to encompass developmental and clinical psychologies and more recently also neuropsychology and behavioral economics. Especially in the last two decades the theory has grown into one of the most cited psychological theories of human motivation and wellness and hundreds of empirical papers have been published on the theory, both on its general nature and as applied to various context such as learning and education, workplace

motivation, sports and exercise, games and virtual worlds, health care and psychotherapy as well as cultural and religious socialization.

While the metatheory or basic orientation behind SDT emphasized the inherently active and growth-oriented nature of human beings, six more specific and empirically testable mini-theories have been developed around which the theory is organized (Ryan & Deci, 2017).

The oldest mini-theory within SDT is the *cognitive evaluations theory* (CET) that focuses on how social environments facilitate or undermine intrinsic motivation, and through that, high-quality performance and well-being (Deci & Ryan, 1980). According to CET, when extrinsic rewards, evaluations, surveillance, or feedback are perceived as controlling, this leads to a more external perceived locus of causality and thwarts the person's sense of autonomy and intrinsic motivation. This is often harmful as research has shown that when people are intrinsically motivated, they tend to learn more deeply, be more creative, be more persistent, and perform better in tasks requiring high-quality engagement. At the same time, research has identified other features of the environment that similarly affect intrinsic motivation such as how much information the person has about one's performance and how much competence one experiences. CET thus deals with how environments affect experiences of both competence and autonomy, and thus support or undermine intrinsic motivation.

Organismic integration theory (OIT), the second mini-theory of SDT, describes the process of integration through which extrinsically motivated behaviors can become autonomous. According to the theory, humans have inherent tendencies to internalize and integrate social and cultural regulations, but certain factors in the environment can promote or inhibit this process of integration. OIT distinguishes between amotivation, and four types of extrinsic motivational regulations: *external regulation* is focused on complying with externally controlled rewards and avoiding punishments; *introjected regulation* is about internally controlling one's behavior related to contingent self-esteem and avoidance of guilt; *identified regulation* is motivation driven by personal valuing and finding worth in actions and *integrated regulation* describes motivation that is fully self-endorsed and well assimilated with one's other values and identifications. The regulations form a continuum (e.g. Ryan & Connell, 1989) and vary systematically in their relative autonomy, with the latter ones being more autonomous and accordingly typically associated with higher quality behavior and persistence. Although need-supportive conditions such as providing meaningful rationale and highlighting choice facilitates more autonomous forms of internalization, conditions that thwart need satisfaction can inhibit such internalization and anchor motivation in more controlled forms.

Causality orientations theory (COT) a third mini-theory, focuses on the personality aspects of SDT and the individual differences in how people orient to their environment. Three general causality orientations are recognized within COT (e.g. Deci & Ryan, 1985b): Autonomy orientation means a propensity to organize behavior by orienting toward one's interests and values, and finding and generating contexts that support them. In contrast, controlled orientation means a propensity to pay attention to social controls and reward contingencies and organize one's behavior by either complying or aiming to defy them. Impersonal orientation, in turn, refers to a tendency to focus on obstacles, and lack of personal or general control over outcomes. The research has looked at differences between

people as a function of how much they emphasize each of these three orientations, and how these orientations can be triggered by motivational primes. The findings in general point toward autonomy orientation, as compared to the two other orientations, leading to more autonomous engagement, more need satisfaction, and better well-being, among other positive outcomes. For example, people high in autonomy orientation can better maintain their intrinsic motivation even when faced with externally controlled contingent rewards (Hagger & Charzisarantis, 2011).

Basic psychological needs theory (BPNT), the fourth mini-theory, aims to identify the innate psychological needs the satisfaction or thwarting of which significantly influences human growth, integration, and wellness. Psychological needs are understood as necessary nutriments that humans universally need for ongoing psychological development and wellness. BPNT has thus far recognized three such needs: autonomy as a sense of volition and internal locus of causality, competence as a sense of effectance, mastery, and growth, and relatedness as a sense of being connected to and cared for by others. Research has shown that all three of these needs have a direct relation with well-being, explaining together a significant amount of variance in people's sense of wellness, vitality, and meaningfulness. A similar pattern of results – need satisfaction leading to wellness – has been found both when looking at between-person differences and within-person fluctuations of need satisfaction (e.g. Reis et al., 2000), and also cross-culturally, and in various contexts ranging from athletes to students and employees.

The fifth mini-theory, *goal content theory* (GCT), looks at what aspirations people have in life and how the nature of these goals affects their wellness. GCT shows that people's life goals can be organized into two empirically distinguishable groups, intrinsic and extrinsic (e.g. Kasser & Ryan, 1996). Intrinsic goals are rewarding in their own right and closely associated with psychological needs while extrinsic goals are more closely connected to contingent satisfactions and approval. Typical intrinsic goals are personal development, community involvement, and meaningful relationships while typical extrinsic goals include wealth, fame, and attractive image. The research consistently shows that both aspiring for and attaining intrinsic goals is positively associated with well-being, while aspiring for and attaining extrinsic goals typically either has no relationship with well-being or is even positively associated with certain forms of ill-being (e.g. Niemiec et al., 2009).

The newest mini-theory within SDT is *relationship motivation theory* (RMT) that focuses on what makes high-quality interpersonal relationships possible. It especially looks at how respect for autonomy facilitates such high-quality relationships and how autonomy and relatedness are intertwined and synergistic in truly responsive, mutually satisfying relationships. RMT suggests that people have an intrinsic need to seek relationships, but while experiencing autonomous motivation within one's relationship contributes to high-quality relationships and both participants' well-being, factors such as conditional regard can hurt both the quality of the relationship and well-being of the partners (e.g. Knee et al., 2005).

Emerging areas for research on SDT include the neurological underpinnings of intrinsic motivation (e.g. Murayama et al., 2010) as well as how autonomy-supportive and need-satisfying developmental environments give rise to "the better angels of our nature" and more orientation to prosociality (e.g. Martela & Ryan, 2016), while chronic need thwarting can conduce to various psychopathologies and the darker elements of human nature such as prejudice, selfishness, and aggression.

While SDT originated in the United States, it has been increasingly studied cross-culturally, with research demonstrating that the basic tenets suggested by the theory, such as internalization and autonomy being related to well-being, hold not only in Western countries, but across cultures and societies (e.g. Chirkov et al., 2003). Accordingly, the theory claims to have identified conditions for psychological wellness, growth, and flourishing that are part of the human nature and not just cultural. This makes SDT not only a descriptive theory of human behavior, but also a normative theory that can be used to evaluate various contexts – such as organizations, societies and cultures – for how autonomy-supportive and need-satisfying these contexts are. In this sense, the theory has been used to make recommendations about how to optimally structure schools, clinics, workplaces, and societies more broadly to support engagement, vitality, wellness, and flourishing.

Self-efficacy Theory

Thomas I. Vaughan-Johnston and Jill A. Jacobson

Queen's University, Canada

In the late 1970s, Albert Bandura (see Albert Bandura) developed a social learning approach intended to provide a unifying theory of successful coping and goal achievement. Research on self-efficacy (see Self-efficacy) expanded over subsequent decades, and by 2019, Bandura's two seminal self-efficacy publications (1977, 1982) alone had over 88,000 academic citations, spanning applied research to theoretical insights.

Bandura theorized that goal striving required at least two fundamental ingredients: (1) *outcome expectations* reflect one's belief that adequately performing a specific behavior will lead to a specific outcome, and (2) *efficacy expectations* reflect one's belief that one can exert those specific behaviors in the first place. In other words, outcome expectations are the belief that effective methods exist to complete tasks (i.e. contingency or cause-outcome beliefs), and efficacy expectations reflect the belief that one can personally use those methods effectively (i.e. competence or mastery beliefs). Although Bandura was clear on the distinction between the two components, subsequent use of the term self-efficacy has not been. Self-efficacy often gets used interchangeably with controllability, which can cause some confusion in the literature particularly in the form of conflicting results. As Ellen Skinner (1996) explains, self-efficacy originally referred only to efficacy expectations but has evolved to integrate both outcome and efficacy expectations (although studies seldom explicitly manipulate or measure both). Thus contemporary usage of self-efficacy assumes that perceiving contingency between actions and consequences is inherently part of having self-efficacy.

Theory Issues in Measurement

In accordance with this modern usage, measures of self-efficacy like the Self-Efficacy Scale (Sherer et al., 1982) clearly mix contingency and competence. Consider the item "When I make plans, I am certain I can make them work." Endorsement of such a proposition implies believing both that plans have a meaningful likelihood of affecting subsequent

tasks (outcome expectations) and believing that one can enact such plans with reasonable competence (efficacy expectations).

Self-efficacy theory posits that self-efficacy beliefs can be very specific (e.g. computer self-efficacy, Compeau & Higgins, 1995) or very generalized (e.g. Sherer et al.'s Self-Efficacy Scale). Content-specific scales that measure perceived competence in particular domains may yield greater predictive utility, and the more specific, the better. For example, dividing teaching self-efficacy into separate subscales measuring teachers' confidence in managing student behavior, effectively providing instruction, and inclusively engaging all students in learning (Tschannen-Moran & Woolfolk Hoy, 2001) yielded important distinctions that would have been lost using a more generalized measure (Klassen & Chiu, 2010). The subscales varied uniquely across classroom teaching level (higher management and engagement self-efficacy for people teaching lower grade levels) and teacher gender (women had lower management self-efficacy than men), with lower self-efficacy predicting lower job satisfaction. These results align with self-efficacy theory's prediction that self-efficacy beliefs can be quite specific to particular contexts and/or tasks.

Another important theoretical question is the relationship between self-efficacy and other self-constructs – in particular, self-esteem. Sherer et al. (1982) have explored the degree of overlap between self-efficacy (beliefs about one's capability of successfully executing a behavior) and self-esteem (the degree to which one evaluates oneself favorably; see Self-esteem, theory of). The Self-Efficacy Scale is moderately associated ($r = .51$) with trait self-esteem, indicating important overlap without suggesting that the constructs are interchangeable. The theoretical distinction is important because self-efficacy and self-esteem often are confused, presumably because they both involve positive perceptions of the self – either as *competent* (self-efficacy) or as *good* (self-esteem). This confusion is evident in Heatherton and Polivy's (1991) popular state self-esteem scale (see Self-esteem, Assessment of), which contains items such as "I feel confident about my abilities." The Self-Efficacy Scale also is positively correlated with internal locus of control (see Locus of Control) and social desirability (see Social Desirability).

Antecedents

Bandura (1977) suggested four antecedents of self-efficacy. *Performance accomplishments* increase self-efficacy when individuals reach specific success conditions, suggesting to such actors their own underlying ability at a task. *Vicarious experiences* involve modeling by skilled individuals, such as when watching a target person complete a task without major setbacks occurring makes the task seem more doable. *Verbal persuasion*, such as simply being told that one is "useless" or "highly capable," can influence global self-efficacy. *Physiological factors* also may affect self-efficacy because people might use stress/anxiety responses as clues to judge their capability. Although these factors can influence self-efficacy over time, Bandura (1997) actually hypothesized that self-efficacy should be quite stable across the lifespan. Nonetheless, Klassen and Chiu (2010) point to several investigations demonstrating changes in self-efficacy attributable to interventions such as teacher-training programs and years of career experience.

Theoretical Impacts

Self-efficacy has played a role in several psychological theories, of which we provide only a few influential examples. Self-efficacy was key in developing the theory of planned behavior (TPB; Ajzen, 1991), an important theory in attitude-behavioral research. TPB mapped the independent roles of attitudes (positive or negative evaluations of the behavior), subjective norms (beliefs about how the behavior is evaluated by people personally important to the actor), and perceived behavioral control (how capable the actor believes himself or herself to be of engaging in the particular behavior, or self-efficacy) in predicting the likelihood of forming behavioral intentions and consequently engaging in that behavior. Perceived behavioral control plays two roles in the model: An increased sense of behavioral control increases the intention to engage in a behavior, and it also can influence the probability of engaging in the behavior independently from intentions. Both paths make intuitive sense: People should be less likely to form intentions to engage in behaviors that they believe themselves to be incapable of performing. But even with a firm intention to perform some action, people who believe themselves incapable of succeeding are unlikely to follow through with their intentions. Ajzen (2002) later explicated how self-efficacy factors into the TPB, with both self-efficacy and controllability (the extent to which a behavior's performance is in the actor's control in the first place) separately contributing to perceived behavioral control.

Self-efficacy also is relevant to the reformulated helplessness theory of depression (Abramson, Seligman, & Teasdale, 1978). According to this theory, people become depressed to the extent that they learn that environmental contingencies cannot be controlled. Two kinds of helplessness are described: Universal helplessness involves believing that responses and outcomes generally are unrelated in oneself or in others. Personal helplessness involves believing that only one's own actions are ineffectual. As Skinner (1996) explains, universal helplessness is comparable to lower outcome expectations or contingency beliefs ("it can't be done"), whereas personal helplessness is comparable to lower efficacy expectations or competence beliefs ("I can't do it"). Contemporary views of self-efficacy would suggest that both kinds of helplessness are relevant to self-efficacy deficits although only the latter is truly about mastery.

Practical Applications

Self-efficacy theory has generated many interventions and applied studies. A major area of interest with self-efficacy has been enhancing performance. Bandura (1993) has suggested that self-efficacy's positive effects on performance occur through four channels: (1) *cognitive*, such as self-efficacious individuals actually deploying the cognitive skills that they possess; (2) *motivational*, such as self-efficacy increasing beliefs about the possibility of success thus bolstering the application of effort; (3) *affective*, including lower self-efficacy's contribution to depression, which in turn hampers performance; and (4) *selection*, as when self-efficacy leads people to select more productive environments. This framework has great utility for understanding self-efficacy and provides guides for

predicting and influencing self-efficacy's operations. To assist a student with low self-efficacy, for example, one could use approaches that are cognitive (e.g. practicing the deployment of skills that a student actually possesses but is not using), motivational (e.g. providing realistic performance benchmarks to make success appear more possible), affective (e.g. introducing activities that increase positive affect), and/or selection based (e.g. planning with the student to approach environments in which productivity is more likely, such as a quiet study space). Indeed, Zimmerman (2000) reviewed many important consequences of self-efficacy on student performance. Self-efficacious students undertake more challenging tasks and set more ambitious goals, succeed more in course work, persevere more in the face of adversity, experience fewer severe emotional reactions after setbacks, and use more effective learning strategies.

Industrial psychologists have studied how self-efficacy can influence workplace performance in both laboratory and field studies (see Self-efficacy, Career). For example, Sherer et al. (1982) found that individuals with higher self-efficacy were more likely to be employed, had quit fewer jobs in their life, had been fired less often, and were more educated than were individuals with lower self-efficacy. It is easy to raise at least two theoretical hypotheses for these relationships: (1) People who believe themselves incapable of accomplishing tasks are presumably less likely to achieve higher education degrees, and (2) obtaining a university degree makes one feel highly capable both due to the prestige of the accomplishment and because of the objective skills that one acquires through such education. Stajkovic and Luthans (1998) meta-analyzed research from 114 studies and found a strong effect of self-efficacy on work performance. They noted that effects were somewhat smaller in field studies than laboratory studies, but this difference simply could be due to lab settings' additional control of nuisance variables. They also found that self-efficacy played a larger role for simple rather than complex tasks although self-efficacy provided a degree of benefit even for highly complex tasks.

Future Questions

One ambiguity in current self-efficacy research is the causal pathway by which self-efficacy exerts its effects. Although many important consequences of self-efficacy have been detected, the pathway in which they unfold remains unclear. For instance, do self-efficacious individuals set more ambitious goals *because* they are not afraid of emotional negativity in response to failure, or *because* they intend to use more effective learning strategies – thus making those goals seem more realistic? Some exploration of these and other purported mechanisms might be helpful in planning interventions to improve self-efficacy and for greater theoretical understanding of the construct. However, the present literature already offers a great deal of practical and theoretical advice for how individuals can learn – and their mentors, parents, and friends can help them learn – all that they are capable of doing and becoming.

Self-esteem, Theory of

R. Shane Westfall

Western Wyoming Community College

Conceptualized

Self-esteem describes an individual's overall sense of self-worth or value. This evaluation encompasses both feelings about the self (such as, "I am worthy") and emotional states, such as pride or shame. Self-esteem may be differentiated from the self-concept by noting that self-esteem is based on an affective evaluation regarding the self, whereas one's self-concept encompasses thoughts and beliefs about the self. Self-esteem may be global (for example, "I'm a good person") or it may be domain specific (for example, "I'm great at basketball"). Additionally, self-esteem is regarded as a trait that is subject to short-term fluctuations. Thus, some individuals tend to have higher self-esteem than other individuals on a consistent basis. This is *trait* self-esteem, as it reflects an individual's generally tendency. Although trait self-esteem is fairly stable across time, fluctuations often occur based one's personal experiences. For example, should something positive occur, such as receiving a promotion at work, an increase in self-esteem is likely occur. Conversely, one may experience lower self-esteem when an adverse event occurs, such as losing one's job. This self-esteem that is responsive to stimuli is *state* self-esteem, as it reflects the individual's current state.

Measurement of Self-esteem

Self-esteem may be measured with either explicit or implicit measures. Self-report measures are most common. The most widely used measure is the Rosenberg Self-Esteem scale, developed by Morris Rosenberg in 1965. This scale consists of 10 items (for example, "I feel that I have a number of good qualities.") that require participants to indicate their level of agreement regarding themselves. Domain-specific scales have also been developed,

assessing self-esteem in areas such as academics or personal relationships. Overall self-esteem, as assessed by the Rosenburg scale reflects an individual's composite on the more domain-specific measures. State self-esteem may be manipulated for experimental purposes in the laboratory. For example, directing participants to focus on desirable aspects about their personality tends to create a temporary boost in self-esteem. Conversely, focusing on negative aspects of one's life tends to decrease self-esteem. Studies such as these allow researchers to explore factors that influence self-esteem, as well as examine differential reactions to self-esteem changes.

Since the 1980s, implicit measures of self-esteem have also been employed. These are based on the notion that individuals have cognitive associations that they are not consciously aware of, yet influence their behavior. As a result, individuals are quicker at making associations held more strongly in their memory. The chief advantage of using implicit testing is that it reduces the conscious biases of the participant by reducing their awareness of the relevant task. The most common of the implicit self-esteem measures is the Name-Letter Task, which finds that the more individuals like themselves, the greater preference for selecting letters that are used in their name (Nuttin, 1985).

Theories

Many theories have suggested that self-esteem is a basic human need. For example, Abraham Maslow included self-esteem in his hierarchy of human needs (see Maslow's Hierarchy of Needs), suggesting that psychological health was not possible unless one had the acceptance and respect of both others and him or her self. Humanistic psychologist Carl Rogers posited that many human problems originate from feelings of self-loathing and worthlessness. In his view, self-esteem could be regarded as not only a need, but a human right. Later work by Edward Higgins (1987) explored the theory of self-discrepancy, positing that individuals have multiple representations of the self, such as the ideal self and the actual self (1987). Self-discrepancy refers to the gap between these representations. A large gap between the actual self and the ideal self is associated with low self-esteem. Additionally, as this gap grows, self-esteem becomes increasingly lower (Moretti, & Higgins, 1990).

Early theories centered on the need for self-esteem and what effects variations in self-esteem produced, however these early theories failed to explain why self-esteem developed. More recent work has produced two predominant explanations for the development of self-esteem in humans. Sociometer Theory, advanced by Leary et al. (1995), suggests that humans are inherently social creatures that seek out the support and approval of other humans. As such, humans have developed a "sociometer" that allows one to detect acceptance and rejection by others, translating these as increased or decreased self-esteem. The second primary theory is Terror Management Theory. According to this perspective, humans are unique among animals in that there is conscious awareness throughout the lifespan that death is inevitable (Greenberg, Pyszczynski, & Solomon, 1986). To protect oneself from this paralyzing fear, humans construct beliefs (for example, religion) that provide them a sense of meaning and purpose. Thus, anxiety regarding one's own mortality is reduced through these beliefs.

Correlates of Self-esteem

Self-esteem is correlated with higher expectancies regarding success. As such, individuals high in self-esteem tend to approach challenges more confidently and see challenges as a way to demonstrate their abilities, whereas those lower in self-esteem are often simply hoping to avoid failure. Individuals high in self-esteem tend to be happier compared to people lower in self-esteem. Self-esteem is negatively correlated with a variety of mental health issues, such as depression and anxiety. Self-esteem is positively correlated with both life satisfaction and personal satisfaction from close relationships. Thus, people high in self-esteem tend to report both more stable dating relationships and more happiness within those relationships.

Despite the many positive factors associated with high self-esteem, there are some negative attributes as well. Self-esteem is positively correlated with narcissism, Machiavellianism, and psychopathy. Strong evidence now suggests that high self-esteem is positively correlated with bullying behavior and interpersonal aggression. To explain these seemingly disparate views of high self-esteem, some researchers distinguish between secure high self-esteem and defensive high self-esteem. From this perspective, individuals with defensive self-esteem are harboring insecurities and self-doubt. Thus, they need the constant reassurance of others to maintain their self-worth. This results in behavioral consequences as well, in that men with high self-esteem are most likely to use violence when someone disputes the favorable view that they have of themselves. Additionally, aggression may result when individuals with defensive high self-esteem experience personal failure (Baumeister & Boden,1998).

Gender and Age

Men tend to have higher self-esteem, compared to women. This gap emerges during adolescence and persists throughout middle age; however, this difference narrows in old age. Additionally, both men and women experience age-related increases in self-esteem from late adolescence to middle adulthood. During childhood, one's parents are generally one's primary source of self-esteem. Thus, parenting style can mold the type of self-esteem that one has later in life. The children of supportive parents tend to have higher self-esteem later in life. Conversely, children that have harshly critical parents are more likely to develop defensive self-esteem, as well as lower self-esteem overall. Beyond parental influence, the academic setting is a significant contributor to the development of the self-esteem for school-aged children. During this time, children are easily able to compare their academic achievement to that of other students. This coincides with identity development, as school-aged children generally have extensive social contact beyond the immediate family. Success, both academically and socially, tends to lead to more positive feelings about the self, thus higher self-esteem. Failure and rejection, however, leads to self-doubt and lower self-esteem. After peaking in middle adulthood, self-esteem tends to decrease as one ages. Generally, this decline is modest and is positively correlated with the normal effects of aging, such as declines in general health and cognitive abilities. Additionally, disengagement for the labor force may produce lower self-esteem as a function of lower income.

Ethnic and Cross-Cultural Considerations

Within the United States, a few minor ethnic differences have been reported. Hispanic individuals tend to have lower self-esteem during adolescence, compared to both White and African American individuals. This disparity disappears during early adulthood, however, with Hispanic individuals reporting slightly higher self-esteem in their 30s. African American individuals experience a more rapid spike in their self-esteem during the adolescent years, leading to higher self-esteem compared to White peers (Twenge & Campbell, 2002). Their age-related declines tend to be more rapid as well, however.

Cross-cultural differences have been noted in the literature, although in many cases dissenting results have also, been found. There appears to be a trend for higher self-esteem in individualistic cultures, compared to collectivist cultures. This may be the result of a Western bias in the scales, however, rather than actual differences in self-esteem (Cai, Brown, Deng, & Oakes, 2007). Self-esteem differences between participants from individualistic cultures and collectivist cultures disappear when using implicit tests of self-esteem. This suggests that individuals from collectivist cultures feel the need to present themselves modestly when taking explicit measures.

Public Policy

During the 1970s interest is self-esteem reached a crescendo in the United States, sparking what could be called a "self-esteem movement." Underlying this interest was the notion that most of an individual's problems in life stemmed from low self-esteem, thus increasing self-esteem was seen as a fix for a number of ills. A variety of agencies began programs to increase self-esteem in the United States. Eventually, this increased interest also resulted in increased research, producing both mixed results and smaller than expected correlations indicating that self-esteem was not the miracle cure sought after. Additionally, high self-esteem correlates with many negative human aspects as well, such as feelings of superiority and higher rates of criminal behavior.

Future Directions in Self-esteem Research

Self-esteem is one of the most researched topics in psychology today. Nonetheless, there are still many remaining questions. Some construct drift may have occurred over the years, as various "types" of self-esteem have become identified. This could explain the disparate findings regarding the correlates of self-esteem. Additionally, factor analysis has suggested that perhaps self-esteem is not a unitary construct, but a conglomerate of other independent constructs. For example, research suggest it may be possible to have both high positive self-esteem and high negative self-esteem. Beyond discovering correlates of self-esteem, the greater challenge is establishing causality. For example, the relationship between low self-esteem and depressions is well documented, yet competing directional models exist, each with empirical support.

Self-Monitoring, Theory of

R. Shane Westfall

Western Wyoming Community College

Conceptualized

Self-monitoring is a personality trait defined as the tendency to subjectively monitor one's self-presentation (see Self-presentation Theory/Impression Management), expressive behavior, and nonverbal behavior in order to affect self-perception and public perception. Some individuals pay a great deal of attention to how they are perceived by others, whereas other individuals are less concerned with the impact that they have on others. Thus, some individuals act in a thoughtful, controlled fashion, consciously adjusting their behavior to social situations and others behave more spontaneously. High self-monitors are individuals that closely monitor themselves in social situations and deliberately act in a fashion subjectively thought to impress others. Conscious thought is given to both their own behavior and the behavior of others in this attempt to be perceived favorably. As their behavior is constantly adjusting to meet social demands, high self-monitors are generally regarded as friendlier and more pleasant by others. Additionally, research has found these individuals to be better at emotion regulation and quicker at determining appropriate behavior in new social situations. Conversely, low self-monitors tend to behave in a manner consistent with their own internal states, such as their beliefs or attitudes, regardless of the social context. As such, they often perceive of themselves as consistent and principled, yet others often consider them to be inflexible, uncompromising, and even overly aggressive. Owing to their lack of awareness regarding social situations, low self-monitors tend to open themselves up to more rejection, on both the personal and professional level. As a result, they often experience elevated levels of anger, resentment, guilt, and isolation.

Considerable differences have been found between high and low self-monitors in regards to the formation of their friendship networks. High self-monitors base their friendships on the skill relevant to the social situation. For example, one might have one set of friends for going to the gym and a different set of friends for going out to a nightclub. Generally, high self-monitors do not allow their various social groups to overlap. The benefit of this compartmentalization is that the high self-monitor is generally surrounded by people that are

highly skilled and comfortable in the selected social setting (Snyder & DeBono, 1985). Whereas high self-monitors tend to have many friends, allowing them to engage in differential self-presentation, low self-monitors usually have fewer friends yet behave more consistently with them. Rather than selected for social skills or abilities, low self-monitors generally select friends on how similar others' attitudes are to their own.

A strong relationship exists between self-monitoring and self-presentation. Individuals high in self-monitoring not only pay greater attention to their social surroundings, but also have more conscious awareness regarding how best to present themselves to others. Conversely, individuals low in self-monitoring interpret fewer social clues and engage in fewer acts of self-presentation. High self-monitors may experience self-presentational conflicts in situations lacking audience segregation. If there is a great deal of variation in the types of people encountered in a social situation, the high self-monitor may struggle with finding the appropriate conduct. This is generally not a concern for low self-monitors (Leone & Corte, 1994).

Measurement of Self-Monitoring

Mark Snyder introduced the concept of self-monitoring in 1974. At the time, there was a theoretical clash between personality perspectives, which look for stable personality traits, and theories espoused by social psychologists, which examine the power of the social situation to drive behavior. The theory of self-monitoring advances a perspective consistent with both viewpoints, in that it suggests there is a stable aspect of an individual's personality that is also responsive to the social situation. Thus, self-monitoring theory suggested that the actions of low self-monitors could be best predicted from trait measures, whereas situational factors would best predict the actions of high self-monitors.

Snyder originally developed a 25-item self-report questionnaire to assess self-monitoring (1974). Degree of self-monitoring was assessed using items such as, "I am not always the person I appear to be." and "I would probably make a good actor." Using this original scale, Snyder found that Stanford University students scored significantly higher than psychiatric patients, but significantly lower than professional actors. This original study reported both high test-retest reliability and validity. This measure, however, was subsequently trimmed to an 18-item measure that has demonstrated better psychometric qualities. Later use of factor analysis (see Factor Analysis in Personality Research) has suggested a multifactorial solution consisting of three subconstructs: Acting, Extraversion, and Other-directedness. This had led to ongoing debate as to whether self-monitoring represents a unified, distinct construct. Currently, there are three measures commonly used to assess self-monitoring: the Self-Monitoring Scale (SMS), the revised version (the Self-Monitoring Scale revised, SMS-R), and the Revised Self-Monitoring Scale (RSMS).

Influence of Self-monitoring

Self-monitoring can be quite useful in certain occupations, such as a salesperson, politician, or actor. Additionally, a significant relationship has been found between high self-monitoring and job performance. This is likely the result of the ability to rapidly adapt to changing

circumstances. High self-monitors strive to provide others with what they want, thus they tend to be seen more favorably by superiors or those in an evaluative capacity. This ability to successfully tap into social norm while providing subtle manipulation is often beneficial during the process of employment interviews, leading to greater success on the job market. Although a great deal of within-sex variation occurs, men tend to score higher on measures of self-monitoring than women. This has been put forth as one potential explanation for sex-based disparities at the higher levels of organizational structures.

Mating behavior is also influenced by one's degree of self-monitoring (Snyder, Berscheid, & Glick, 1988. In one study, participants were faced with the dilemma of either dating an individual that was physically unattractive yet possessing desirable personality characteristics or an individual that was physically attractive yet undesirable in personality. Overwhelmingly, high self-monitors selected the physically attractive partner, whereas low self-monitors chose the partner with desirable personality traits. This suggests that high self-monitors not only place a greater emphasis on external cues compared to low self-monitors, but are also more concerned with creating a positive image for others. Additionally, high self-monitors report more dating partners over a given time period, yet low self-monitors tend to have more stable dating relationships. Finally, recent work has found that an individual's degree of self-monitoring affects the mental representation that one forms of their romantic partners (Leone, Gainey, & Moulder, 2016). Low self-monitors form a more positive representation of their current partner and a more negative representation of their former partners in comparison to high self-monitors.

Self-Monitoring and Personality

High self-monitors tend to have higher self-esteem (see Self-esteem, Theory of) compared to low self-monitors. This could be the result of higher levels of social praise given to high self-monitors (Leary et al., 1995). In fact, the criteria for individual self-esteem seems driven by one's degree of self-monitoring. For low self-monitors, depression occurs when there is a sizable discrepancy between the perceived self and what he or she thinks the self should be. For high self-monitors, depression occurs when there is a sizable discrepancy between the perceived self and what he or she thinks is expected by others.

Individual differences in self-monitoring are even reflected in the word-choices that individuals employ (Ickes, Reidhead, & Patterson, 1986). High self-monitors use third-person pronouns (they, them) more frequently when they speak, compared to low self-monitors who tend to use first-person pronouns (I, me) more frequently. This is indicative that high self-monitors place more attentional focus on others rather than the self. Additionally, high self-monitors appear to be more susceptible to groupthink and herd mentality.

Developmental and Biological Factors

School-age children already exhibit a propensity for self-monitoring, although their skills at self-presentation are often primitive. Some empirical work has supported the notion that self-monitoring is not entirely stable throughout the lifespan. Rather, it may peak during

late adolescence and slowly reduce as the individual ages. Clinical research involving patients with lesions suggests that the prefrontal cortex is intricately involved in self-monitoring. Not only is the prefrontal cortex essential for execution of behavior and self-insight, but damage to the prefrontal cortex results in a lack of ability to discern appropriate behavior in social contexts. Even relatively minor disruptions of executive function may hinder self-monitoring, as both variations in circadian rhythm and sleep deprivation are noted to reduce self-monitoring abilities.

Intervention

Self-monitoring is a useful therapeutic technique for a wide variety of academic and behavioral difficulties. These techniques are particularly effective for adolescents and young adults. They have demonstrated efficacy for a range of issues such as self-help (for example, weight loss and better oral hygiene), academic issues (for example, classroom behavior and homework completion), and development of individual social skills. Often individuals, particularly adolescents, are unware of how their behavior affects those around them. Self-monitoring interventions increase understanding of these effects and, in the process, teach individuals increased awareness of their own behaviors. Thus, individuals undergoing self-monitoring interventions often become more altruistic and socially conscious. Another benefit of utilizing self-monitoring techniques is that they can be designed for the individual's specific needs and social setting. As a consequence of increased social sensitivity, there is often a reduction in other undesirable behaviors that were not specifically targeted by the intervention.

Cross-cultural Considerations of Self-Monitoring

Cross-cultural differences have been noted in regard to self-monitoring. As people from individualistic nations place more emphasis on the self, there is there is the expectation that they will engage in less self-monitoring that individuals from collectivist nations. Despite empirical support for this notion, it should also be noted that Snyder's measures of self-monitoring focuses on aspects of the self that predominate American and Australian culture. Thus, later researchers suggest that the scale does not adequately assess self-monitoring in cultures such as Japan and Hong Kong. Additionally, cross-cultural differences regarding self-monitoring may influence relationship satisfaction. Among Western respondents, self-monitoring correlates negatively with relationship quality, however among Eastern samples no significant relationship was found to exist.

Future Directions

Paramount to the future study of self-monitoring is determining whether it exists as a unitary construct, or is merely the summation of the three subconstructs revealed through the original factor analysis. Additionally, there appears to be a great deal of theoretical overlap with social comparison. Recent work has found that the strength of this relationship varies

greatly, depending on which measure of self-monitoring is employed (Soibel, Fong, Mullin, Jenkins, & Mar, 2012). Beyond the question of the relationship between self-monitoring and social comparison, these findings further illustrate the need to clarify precisely what self-monitoring is since there are currently multiple scales for assessing self-monitoring and each produces disparate results. Additionally, there is disagreement about whether high and low self-monitors represent discrete types of individuals or whether these are simply points along a continuum.

Self-other Interjudge Agreement; Theory of Accuracy

Shana M. Needham and Jill A. Jacobson

Queen's University, Canada

Self-other accuracy refers to the consistency in personality evaluations between judges of target individuals and the targets themselves (Funder & West, 1993). In 1955, Lee Cronbach (see Lee J. Cronbach) described four basic types of accuracy. Stereotype accuracy refers to a judge's ability to generalize about a target's outcomes by focusing on the probability of a response. Differential accuracy pertains to a judge's ability to draw distinctions between targets on specific personality dimensions. The remaining two types, evaluation and differential evaluation, represent the central tendency of a judge to make self-judgments as well as the ability to discern differentiation from average evaluations. Cronbach suggested that these components influence assumed similarity between the judge and target because the smaller the discrepancy in each of these four components, the more a target is perceived as comparable to the judge. Indeed, Kahneman and Tversky (1973) found that perceived similarity between judge and target influenced the level of liking between the two and increased judges' confidence in the accuracy of their assessments of a target. Assumed similarity is, therefore, an important component to assessing accuracy.

Many current researchers investigating self-other accuracy argue that Cronbach's ideas may have been misunderstood and misapplied in decades of research due in part to the statistical implications of assessing each component. Furthermore, how to properly measure accuracy has been debated extensively. As a result, researchers have developed several other theoretical models concerning self-other accuracy and how it is obtained.

Social Relations Model

Dave Kenny's (1988) Social Relations Model (SRM) focuses on the judgments by others breaking it down into three components: how the perceiver tends to judge others, how the target typically is judged by others, and how the relationship between the perceiver and target influences the perceiver's evaluation. Kenny argued that to appropriately

evaluate person perception in each of these areas, seven basic components should be considered: consensus (multiple judges agree on their evaluations of a target), assimilation (a judge rates multiple targets similarly), self-other agreement (a judge perceives a target as the target perceives him or herself), assumed similarity (judges view targets as judges view themselves), reciprocity (judges and targets view each other similarly), assumed reciprocity (judges believe targets evaluate them as the judges view the targets), and meta-accuracy (judges are aware of how targets view them). Kenny stressed that consensus should be the most important area of focus in future research because it would help to determine accuracy among judges, but he also emphasized the importance of understanding how the level of acquaintance between two individuals would influence agreement.

Realistic Accuracy Model

In his Realistic Accuracy Model (RAM; see Realistic Accuracy Model), David Funder (see David Funder) argues that self-other accuracy is a complex process based on attribution, observable behaviors, and the perceptions of the judge. According to this model, the observability of a trait cue, the detection of that cue, and use of the cue in a given interaction will dictate the extent to which individuals accurately judge a target. In other words, accuracy combines judges' and targets' abilities to exhibit and identify clues during an interaction. Therefore, greater accuracy can result in one of four ways: (1) better information is given during the course of an interaction, (2) traits are more overt, (3) a target is easier to judge, and/or (4) a judge is simply better than others (Funder, 1995). Building upon these four components, Funder proposed that they occur in a specific sequence in that a target's trait is elicited by the context and produces a specific behavior, and then that behavior must be available for detection, evaluated, and correctly understood by a judge. Each of these steps elicits a unique set of problems because if the behavior is not overt enough or the judge is not paying attention, then the probability of making accurate judgments decreases.

Funder and West (1993) argue that the combination of these factors is important because integrating all this information facilitates accurate predictions of future behaviors within a given context and aids in the development of intimate relationships. The more successful people are at the four stages of the RAM, the more likely that a particular personality trait is to be used to correctly assess behavior. The assumption of judges then is that behaviors produce information about the underlying personality and, therefore, help in understanding what an individual will do in the future. The ability to predict behaviors is important for the development of relationships because greater self-other agreement between individuals produces greater liking of others, and as a result, more favorable relationships develop (Human, Sandstrom, Biesanz, & Dunn, 2012).

Self-Other Knowledge Asymmetry Model (SOKA)

The SOKA model deviates from the previous two models in that it does not simply focus on judges' accuracy about targets but instead makes predictions based on differences in knowledge and motivation in the assessment of the self vs. others. Vazire (2010) proposed and found that self-ratings are more accurate than other-ratings for traits that are low in

observability and evaluativeness, but others are more accurate than selves for traits that are high in evaluativeness because ego-protective and social desirability concerns bias self-ratings. Self- and other-ratings did not differ significantly in accuracy for traits that are high in observability and low in evaluativeness. Vazire also found that level of acquaintance moderated these effects with friends being more accurate than strangers for traits that were low in observability and either high or low in evaluativeness.

Further exploring the SOKA model, Beer and Vazire (2017) examined how valid self-other judgments are regarding the Big Five personality traits. They used reports from targets, a knowledgeable judge, and an acquaintance judge as well as electronically activated recorders to assess environmental noises to determine accurate evaluations. Judges relied more on behavioral cues to assess behavior, where extraversion, neuroticism, and openness were assessed most accurately from behaviors. Self-reports of behaviors predicted only extraversion.

Current and Future Research

Given that each theoretical perspective proposes different goals in person perception, three main research questions began to dominate the field: When do multiple judges of a target agree with each other (i.e. consensus)? When do a judge and target agree about evaluations of the target (i.e. self-other agreement), and when are the judgments reflective of actual characteristics (i.e. accuracy)? Although the aforementioned paradigms have continued to narrow down how and when these questions can be answered, there is still debate concerning how and if moderators exert influence on self-other accuracy and the extent that intimacy influences accuracy and consensus.

Moderators of self-other accuracy may be hard to identify because of the complexities of the judgment process. Greater psychological adjustment (defined as a combination of hedonic and eudemonic well-being) was associated with greater accuracy in self-other judgments perhaps because it aids in conveying less observable traits to others (Human & Biesanz, 2011). Women have a slight accuracy advantage over men in cross-sex relationships (Allik, de Vries, & Realo, 2016), but age effects have been inconsistent (i.e. yielding greater agreement or having no effect).

Interestingly, the length of acquaintance may be a more complex variable than once thought because the association between length of relationship and accuracy is not linear (Brown & Bernieri, 2017). At zero acquaintance, extraversion, conscientiousness, openness, and agreeableness were judged accurately. As expected, accuracy in trait judgments increased for all Big Five personality dimensions after a brief get-to-know-you interaction, but significant increases in accuracy were not detected after interactions during three classroom sessions for a 10-week academic course. Therefore, more research is needed to address the nature of the relationship between accuracy and intimacy. Additionally, research should extend further into how individual characteristics influence the ability to convey and judge traits accurately.

Finally, researchers are returning to early interests in cognitive processes and examining neurocognitive mechanisms associated with self-other agreement. For example, Zhao and colleagues' (2016) found that oxytocin plays a role in the way that self-relevant information is used when making accuracy judgments because it reduces self-centered behaviors.

Self-Presentation Theory/Impression Management

Austin Lee Nichols

University of Navarra

Impression management (IM) is the act of controlling the impressions one conveys to an audience (Schlenker, 1980). It is not limited to acts involving deception, and instead includes any act, conscious or nonconscious, intended to convey a particular impression – about the self or others – to a particular audience. For example, people often manage others' impressions to help these others accomplish their impression management goals (Schlenker & Britt, 1999). In addition, an audience may not actually contain other people; it may be an imagined audience, or it may be the "self" as an audience (Schlenker, 1980). When attempting to manage only one impression to one audience, people are often successful, and even young children can effectively convey a single desired impression (Hatch, 1987).

In 1959, Erving Goffman published the influential book, "Presentation of self in everyday life" followed by "Strategic interaction" in 1969 (Goffman, 1959, 1969). In these and other writings of his, he lays the foundation for several concepts including impression management, roles, and the dramaturgical perspective. In doing so, he suggests that life is like a play and we are all actors. We play roles based on what is expected of us and what we want to accomplish in any given interaction. As in theater, he suggests that we also use scripts, props, and do our best to set the stage to make for the most successful performance possible.

Stemming from this broader concept of impression management, self-presentation focuses on the ways people attempt to present themselves to others (Leary, 1995). When people are aware of the desired image they seek to convey to a particular audience, they can systematically use various self-presentational tools to choose what to say and how to act to convey the desired image. The more extreme the impression, the easier it should be to convey. For example, when politicians want to convince people from their party that they are likeminded, they can simply act and talk in ways that correspond to the views of that party.

Multiple Audience Problem

People may also face more complicated self-presentational situations. For example, the multiple audience problem occurs when a person faces two or more audiences and desires to convey a different impression to each audience. An "audience", in this case, can be any number of

people to whom the person wants to convey a specific impression. One example is when a teenage boy goes to dinner with his mother and his girlfriend and likely wants to convey different impressions to these two audiences (e.g., responsible to his mother and carefree to his girlfriend). Expanding on the example from above, politicians in a two-party system often want to convey one impression (e.g., a conservative) to all members of their party and another impression (e.g., a moderate) to all voting members of the other party. Therefore, the "problem" involves the possibility of conveying the wrong impression to the wrong audience, and may result in negative consequences (e.g., lost trust). To be successful in the multiple audience problem, people must convey or maintain all desired impressions to all intended audiences.

After years of research on people's ability to simultaneously convey multiple messages, Fleming (1994) theorized about the desire to present multiple impressions of the self, arguing that people are often successful in these multiple audience problems. In one of the first examinations of this phenomenon, Van Boven, Kruger, Savitsky, and Gilovich (2000) measured participants' success and confidence in these situations and, for the first time, empirically examined multiple impressions. These researchers asked "actor" participants to present one impression (i.e., an extremely studious individual) while alone with one person and then the opposite impression (i.e., a reckless party animal) while alone with a second person. Each actor then interacted with both audiences together and received instructions to preserve both impressions. In general, people successfully maintained each desired impression (as measured by audiences' impressions of the actor). In addition, participants were overconfident in their ability to convey the two different impressions simultaneously. That is, actors expected to convey stronger impressions than they actually did.

Most recently, Nichols and Cottrell (2015) examined factors affecting self-presentational success in the multiple audience problem. Participants arrived in groups of three, and experimenters assigned one participant to play the actor while the other two participants served as audiences. In each interaction, experimenters gave specific instructions to the actor regarding which impression(s) to convey. In one condition (i.e., the familiar audiences condition), actors conveyed an impression individually to each audience and then attempted to preserve the different impressions in front of both audiences. In a second condition (i.e., the unfamiliar audiences condition), actors conveyed different impressions to two audiences simultaneously without first establishing the impressions with those audiences in prior interactions. Participants also either conveyed extreme positions or more similar, moderate positions. In general, audience familiarity and the discrepancy of the impressions affected self-presentational success in the multiple audience problem (i.e., the ability to convey both impressions simultaneously). People were more successful in the multiple audience problem when they faced familiar audiences than unfamiliar audiences and when they conveyed similar rather than discrepant impressions.

Strategies and Tactics

Although an agreed upon comprehensive list has not yet emerged, several scholars have focused on the tactics, or strategies, used to convey a specific impression. One of the most widely used and first list of tactics emerged from the work of Jones and Pittman (1982). Their taxonomy of impression management techniques included exemplification,

ingratiation, intimidation, self-promotion, and supplication. Exemplification is when individuals attempt to appear moral and having integrity by acting honest, self-sacrificing, and generous. Ingratiation involves things such as doing favors, flattery, or agreeing with someone else to appear likable. Intimidation is seen in anger and aggression toward others in an attempt to appear dangerous. Self-promotion refers to behaviors aimed at trying to make oneself appear competent, as in an interview-type situation. Last, supplication occurs when individuals present the impression of vulnerability through acts of weaknesses. Additional tactics discussed in the literature include excuses, apologies, justifications, disclaimers, self-handicapping, entitlement, sandbagging, enhancement, and blasting (Gibson & Sachau, 2000; Lee et al., 1999).

Detecting IM in Self-Report Responses

One common problem involved in using self-report surveys or questionnaires (for research or practical purposes) is that people may respond in a purposeful manner to convey a desired impression. Much research has focused on detecting these respondents, and two main scales are often used to do so. The first measure is the Social Desirability Scale (Crowne & Marlowe, 1960) while the second is the Balanced Inventory of Desirable Responding (Paulhus, 1991). Both scales seek to detect participants who disproportionately deny common negative thoughts or behaviors or assert uncommon positive ones. In general, these scales are successful at detecting "faking" on self-report measures, and are useful for academics and practitioners alike (Paulhus, Bruce, & Trapnell, 1995).

Future Research

Despite the plethora of research focused on these issues in the 1980s and 1990s, research on impression management has been largely ignored for the past two decades. As such, there still exist several opportunities for IM research to benefit various academic and practical fields. This includes further examining how impression management looks and works in organizational contexts, including with leadership, customer service, and hospitality, just to name a few. In addition, a better understanding of impression management in marketing and advertising will likely benefit those doing research and using these concepts in practice. Finally, gaining an overall better understanding of why and how we change our behaviors to manage impressions can be useful to researchers and practitioners in a variety of settings.

Social Learning Theory/Social Cognitive Theory

Zahra Vahedi

Ryerson University

Conceptualization and Overview

Social learning theory was developed from the works of Albert Bandura in a period where behaviorism was one of the dominant theoretical lenses through which human behavior was explained. In contrast to the strict stimulus-response association that most behaviorist theories adhered to, social learning theory acknowledged the role of *cognitions* – such as our thoughts – in the process of learning. This varies greatly from the sole emphasis on behavior based on stimuli and automatic responses that other models of learning posited, as well as the strict rules of enforcement schedules that were deemed necessary for behavior to occur. Indeed, Bandura essentially merged behavioral and cognitive theories to provide a model of learning that incorporated behavioral, cognitive, and environmental elements. This emphasis on cognition was more apparent when Bandura further developed and renamed his original social learning theory as social cognitive theory. The emphasis on cognitive processes does not detract, however, from the role of the observing individual as well as environmental factors. Rather, social learning theory incorporates all three components as explanatory mechanisms that drive the acquisition of behavior.

Social learning theory was realized following a series of seminal experiments by Bandura and his colleagues involving Bobo dolls. In their first experiment, Bandura and his colleagues exposed children to an adult of either the same or opposite sex, either playing aggressively or non-aggressively with a Bobo doll. The children were then allowed to play with the Bobo dolls themselves, and it was identified that the children were more likely to play aggressively with the dolls if the adult they had watched had also played aggressively with the doll. These results were also replicated in a later study, where children viewed either violent or non-violent videos, and were then allowed to play with the Bobo doll. Children who viewed the violent videos were similarly more likely to play aggressively with the doll. These results thereby highlighted the role observation – of either interpersonal behavior, or through media images – plays in the modeling of behavior. In addition, these

results suggest that (1) behavior can be learned solely through observation, and (2) the acquisition of this behavior does not require any additional reward or reinforcement.

Based on his findings, Bandura also highlighted the cognitive processes – or principles – involved in the observation of behavior, which ultimately influence whether modeling of that behavior will occur. According to Bandura, there are four stages – or components – that are required for successful learning. First, individuals must *attend* to the behavior being modeled. Various characteristics – such as the novelty of the behavior, or its relevance – influence the likelihood that the observer will pay attention to it. Furthermore, it is quite likely that a behavior that is not attended to will not be imitated. Characteristics of the individual modeling the behavior – such as how closely the observer identifies with them – also influence whether the behavior will be attended to or not. For example, a female observer would be more likely to model behavior that is demonstrated by another female. Second, the *retention* of the behavior will influence how well it will be replicated. In other words, the degree to which the observer can remember the specifics of the behavior influences how well it is modeled. Both features of the observer – such as their own cognitive capacity – as well as those of the behavior – such as how complex the act is – will influence the degree to which the behavior is modeled. The behavior that was modeled is then *reproduced* by the observer; feedback from others can help the individual adjust the behavior at this stage. Reproduction of the behavior not only depends on the cognitive capabilities of the individual, but also the physical or sensorimotor skills required to implement the behavior. Finally, differing *motivations* will influence whether the behavior is reproduced or not. By evaluating whether production of the behavior results in rewards or not – and whether these rewards outweigh any costs – the individual's motivation to replicate the behavior will be affected. These motivations often involve the environmentally enforced rewards or costs associated with the behavior.

Reciprocal Determinism

The central tenet of SLT surrounds the dynamic interaction between the individual's personal influences, such as their cognitions, their behavior, and the environmental; an interaction also referred to as "triadic reciprocability" (Bandura, 1986). In other words, these three factors occur interdependently alongside one another, with mutual effects that influence the cognitions one experiences, the behavior that is produced, or the environment that is sought. As indicated by Bandura (1978, pp. 356–357), "Because people's conceptions, their behavior, and their environments are reciprocal determinants of each other. Individuals are neither powerless objects controlled by environmental forces nor entirely free agents who can do whatever they choose." Here, Bandura is suggesting that the interplay between these three factors is nuanced and fluid; one's cognitions might influence the way an individual behaves across different environments, or an individual's behavior might elicit varying responses from the surrounding environment. For example, a child that is disruptive in class might elicit negative feedback from his or her teacher and classmates, which in turn results in the child becoming cognitively aware of the negative reaction from the environment and, ultimately, influences future behavior.

This concept contrasts with the learning and personality theories that were predominant during the period of Bandura's research; specifically, these theories generally

conceptualized the forces that influenced behavior as having independent effects and being non-interactive. For example, Skinner's theory of learning posited a direct stimulus-response method of behavior acquisition, with no attention given to the role of cognitions in this process. In other words, behavior was proposed to be solely shaped by environmental stimuli, with the responsive behavior occurring automatically without any cognitive input. Similar to SLT, Skinner also posited that the likelihood of a particular behavior being learned depended on the reinforcement – either positive or negative – associated with it.

Self-efficacy

The notion of self-efficacy refers to "people's judgments of their capabilities to organize and execute courses of action required to attain designated types of performances" (Bandura, 1986, p. 391). In other words, self-efficacy refers to the belief an individual has in their capability to complete a certain task. As a result, self-efficacy levels greatly influence the *motivation* – and ultimate achievement – of a certain behavior. If one does not believe that they are capable of performing a task, they will consequently have little motivation to perform it as well. As posited by Bandura (1997), "people's level of motivation, affective states, and actions are based more on what they believe than on what is objectively true" (p. 2); therefore, self-efficacy beliefs are a critical component in driving the completion of a task, even when considering an individual's existing skill levels. Furthermore, self-efficacy has been posited to be composed of three different dimensions (Bandura, 1977a, 1977b): self-efficacy *magnitude* refers to the level of difficulty of the task itself. For example, an individual might feel capable of performing a low magnitude tasks – such as sending an email – but have lower self-efficacy in completing a high magnitude task – such as completing a manuscript. The second dimension is the *strength* of self-efficacy, or the level of confidence the individual has about performing the task. Finally, *generality* refers to the extent in which a self-efficacy belief is generalizable to other situations or domains (Cecil & Pinkerton, 2000; Van der Bijl & Shortridge-Baggett, 2001).

Sources of Self-efficacy

According to Bandura (1977b, 1982) several factors are known to influence one's level of self-efficacy; specifically, four factors have been posited to be used by individuals to determine their self-efficacy for a specific task. First, *performance outcomes* – or the previous experience one has with the task – is proposed by Bandura (1977b) to be the most important source of self-efficacy. Experiences in which an individual has previously achieved success will likely lead to a greater sense of competence for that particular task, as well as related ones. Second, *modeling* – or *vicarious experience* – also influences one's level of self-efficacy; seeing other individuals – especially others who one can relate to – succeed at a given task increases one's own levels of self-efficacy. Alternatively, one's self-efficacy decreases when we see other individuals fail at performing a given task. The third factor, *verbal* or *social persuasion*, refers to the positive or negative reinforcement one receives from other individuals. Encouragement from others regarding one's performance on or ability to perform a given task often leads to increases in self-efficacy, whereas

discouragement can result in decreases. Encouragement can also result in greater sustained self-efficacy when the individual is faced with challenges in completing the task. Finally, *physiological feedback* – or *emotional arousal* – refers to the physiological sensations individuals experience and the influence they can have on one's levels of self-efficacy. For example, physiological sensations such as anxiety and sweatiness can result in decreased perceptions of self-efficacy for a task.

Vicarious Reinforcement

In addition to simply learning through observation, Bandura also suggested that observers are influenced by the reinforcements provided to the modeler of the behavior. Specifically, these reinforcements can take the form of punishment or rewards as consequences for the behavior, with the observer inferring similar reinforcement if they were to engage in the behavior as well. Furthermore, it is posited that behaviors that are rewarded are more likely to persist, whereas those that are punished will be discontinued. Bandura explored the concept of vicarious reinforcement through another Bobo doll experiment. In this version, Bandura (1963) again presented videos of a model playing aggressively with a Bobo doll. In one of the experimental conditions, the video showed the model being rewarded for their behavior; in the second experimental condition, the model was punished with an admonishment. Finally, in the control condition, the video ended immediately after the model finished aggressively acting with the Bobo doll. The children were then allowed entry into a room with toys, including the Bobo doll. The results of the study found that the children who had viewed the model being punished for the aggressive behavior were less likely to play aggressively with the Bobo doll than those who had viewed the video of the model being rewarded. These results indicate that observed behavior that is rewarded is more likely to be imitated, whereas behavior that is punished – also referred to as vicarious punishment – is less likely to be modeled. The concept of vicarious reinforcement can be applied to various real-life settings, and most notably has been used in educational environments (e.g. Kazdin, 1973, 1981).

Terror Management Theory

Terror Management Theory (TMT; Greenberg, Pyszczynski, & Solomon, 1986; Solomon Greenberg, & Pyszczynski, 2015) draws upon thinkers such as Sigmund Freud, Otto Rank, Robert Jay Lifton, and Ernest Becker, to provide a comprehensive analysis of how the knowledge of mortality and fear of death influences human behavior.

TMT proposes that humans, like other animals, are predisposed to strive for survival and to avoid death. However, unlike other animals, humans are aware of their inevitable mortality. This awareness, coupled with a drive for self-preservation, creates the potential for paralyzing anxiety, or terror. According to the theory, human beings avoid feeling this terror by sustaining faith in *cultural worldviews*. Cultural worldviews are belief systems that provide a basis of meaning and significance that allow humans to feel like they may transcend death, either literally (through afterlife beliefs), or symbolically (by leaving a lasting impact on the world though group identification, relationships, children, or other life achievements). When people live up to the standards of cultural worldviews, they can attain a sense of self-esteem – the feeling that one is a valuable member of a meaningful universe. According to TMT self-esteem protects people from feeling death anxiety.

To understand how the need for self-esteem develops, it is important to consider socialization processes (Becker, 1973). Humans are born helpless and dependent on their parents for protection, warmth, and love, to help sooth their anxiety and fears. Over their first few years, children learn that in order to retain love and approval from their parents they need to adjust their behavior to meet their parents' expectations. This desire to live up to the standards outlined by our parents is the initial impetus for a need for self-esteem. When children live up to the standards, they feel worthy of love and protection. In this way, self-esteem becomes an anxiety-buffer, a primary basis of psychological security. As children develop the capacity for symbolic thinking, and learn about death, they come to realize that

their parents are also fragile and mortal, and that they cannot protect them from death. At this point, the bases of self-esteem transfers from living up to standards set by parents to standards set by larger cultural structures (e.g. one's nation or religion). Individuals vary on how successful they are at meeting the expectations set forth by their worldviews. Those who are more successful tend to have higher and more stable self-esteem, while those who are less successful tend to have lower and less stable self-esteem.

Support for Terror Management Theory

Support for TMT has been found in over 500 studies across over 25 countries. Three major hypotheses have guided most TMT research. The first is the *mortality-salience* hypothesis, which states that if a psychological structure (e.g. self-esteem, cultural worldviews) protects people from anxiety about death, then reminders of death should increase their need to defend and bolster that structure. This hypothesis has received wide empirical support (for a review see Greenberg, Vail, & Pyszczynski, 2014). For example, studies have shown that after thinking about death participants are more likely to defend their cultural worldviews (e.g. Greenberg et al., 1990) or strive to enhance their sense of self-esteem by living up to the standards of their worldviews. In general, after reminders of death, participants will defend their worldviews by praising those who support them and derogate or aggress against those who threaten or challenge them (e.g. Greenberg et al., 1990). This "worldview defense" has important implications for intergroup relations. However, individual differences affect the nature of these defenses in that they depend on the individual's internalized worldview. For example, after reminders of death, political conservatives become more supportive of conservative candidates, whereas political liberals become more supportive of liberal candidates. Likewise, mortality salience leads religious individuals but not atheists to endorse more strongly religious beliefs.

TMT proposes that the mortality-salience effect occurs through a dual process in which death-related thoughts are first pushed out of consciousness by *proximal* defenses, such as denial, distraction, or rationalization. After death thoughts are suppressed, they are still accessible, but no longer conscious, and people engage in *distal* defenses. Distal defenses include maintaining self-esteem and faith in one's cultural worldview, which ultimately give people a feeling of protection and hope for immortality (e.g. Pyszczynski, Greenberg, & Solomon, 1999).

Although a typical mortality-salience induction asks participants to consciously think about and write about their own death, mortality salience has been induced in a variety of ways including subliminal priming of death-related words, exposure to death-related images, terrorism, natural disasters, and proximity to cemeteries. Importantly, the effects of mortality salience appear to be unique to death-related cognitions, rather than other aversive topics (e.g. intense pain, meaninglessness, failure, general anxiety, uncertainty, and social exclusion).

A second hypothesis, the *anxiety-buffer* hypothesis, states that if a psychological structure (e.g. self-esteem, cultural worldviews) buffers anxiety, then validating or boosting this structure should reduce anxiety in response to subsequent threat. If self-esteem provides a buffer against death-related concerns, then those with high levels of self-esteem should be

less susceptible to reminders of death. In support of this hypothesis, researchers have found that those with high dispositional self-esteem, or temporarily elevated self-esteem, report less anxiety in response to graphic death images and while anticipating electric shocks (Greenberg et al., 1992), and engage in less defensive responses after a reminder of their mortality (e.g. Harmon-Jones et al., 1997).

A third basic TMT hypothesis is the *death-thought accessibility* hypothesis. According to this hypothesis, if a psychological structure (e.g. self-esteem, cultural worldviews) provides protection against death-related concerns, then threatening the structure should increase the accessibility of death-related thoughts. In support for this hypothesis, studies show that threatening one's self-esteem or their cultural worldviews increases the accessibility of death-related thoughts in consciousness (Hayes, Schimel, Faucher, & Williams, 2008; Schimel, Hayes, Williams, & Jahrig, 2007). Death-thought accessibility is commonly assessed using a task in which participants fill out a series of word fragments (e.g. DE _ _) that can be completed with neutral words (e.g. DEBT) or with death words (i.e. DEAD). The more word-stems completed in death-related ways, the closer death-related thoughts are to consciousness.

TMT and Individual Differences

Aside from self-esteem, a variety of other personality variables also have been found to influence how people manage their mortality concerns (see Greenberg et al., 2014). Four personality variables have been extensively studied: authoritarianism, personal need for structure, attachment style, and neuroticism.

Authoritarianism refers to a proneness toward rigid obedience to authority. After reminders of death, those high in authoritarianism become particularly negative toward members of different groups, whereas those low in authoritarianism become particularly tolerant of them.

Personal need for structure refers to preferences for structure and order in one's life. Research has found that mortality salience makes those high in need for structure prone to overly simplified views of themselves, others, groups, and events. In contrast, mortality salience makes those low in need for structure more open to experiences, complexities, and novel cultures.

Attachment style is how one relates to other people. Securely attached people are low in relationship-related anxiety and avoidant tendencies. Insecurely attached people are high in anxiety, avoidance, or both. These attachment styles originally developed during childhood. They moderate responses to mortality (e.g. Mikulincer, Florian, & Hirschberger, 2003). Research has found that reminders of mortality increase reported relationship commitment, thinking about romantic commitment reduces defensive responses to such reminders, and priming relational insecurity increases death-thought accessibility. Studies have also found that after mortality salience, people exaggerate perceptions of how positively their partners view them, are more likely to forgive a partner's hurtful offense, and experience greater distress when imagining partner infidelity. However, the degree to which reminders of death make close relationships more appealing is often moderated by attachment style. Whereas securely attached individuals are more likely to invest in close

relationships as a terror management strategy, persons with insecure attachment styles are more likely to invest in other, more culture related resources for terror management (e.g. Mikulincer et al., 2003). More often than not, secure individuals are able to manage the terror of death in a more efficient way, and experience less anxiety and depression.

Neuroticism refers to a proneness to emotional instability and negative emotions such as guilt, anxiety, and depression. From a TMT perspective, highly neurotic people are not well integrated into meaningful symbolic systems of reality, and consequently for them the body is a continual reminder of their material nature and therefore the inevitability of physical death. For those high in neuroticism, mortality salience therefore decreases the appeal and appraisal of the physical aspects of sex and bodily functions. Furthermore, reminders of sex and the body serve to increase death-thought accessibility. For those low in neuroticism, body reminders are only threatening if participants also read about how humans and animals are not very different (Goldenberg, 2012).

Trait Theory of Allport

Corey F. Doremus

Rowan University

Developing a Common Language

The core concept of personality is dependent upon a certain consistency of behavior in an individual, and for current behavior to frequently be in some meaningful way related to their past behaviors. For disparate behaviors to demonstrate a similarity across time, the motivational structure of the individual must be at least somewhat rigid and constant, and this internal framework is contemporarily discussed as a collection of *personality traits*. Decades before the creation of the Big Five (see FFM and Facets), Gordon Allport examined the commonality between and across human behaviors and developed a theory of personality traits and the extent to which they shape an individual's behavior. It is difficult to completely imagine the field of personality psychology without the common trait names used contemporarily, however the field owes a great debt to the lexical investigations of Gordon Allport. Along with his colleague Henry Odbert, Gordon Allport carefully classified all personality-describing words found in the major dictionaries of his time, forming a list of more than 40,000 words. From this list, the researchers selected the adjectives and found more than 4,000 words which fulfilled these criteria (Allport & Odbert, 1936). This work forms a major basis for the trait names employed today across the field, and the theories which arose from this investigation helped to lay the groundwork for countless personality researchers in the following years.

Varying Roles and Strengths

Gordon Allport's view of traits included various levels of traits with vastly different impacts on external behavior, namely Cardinal Traits, Central Traits, and Secondary Traits. These traits exist in a hierarchy, with Cardinal Traits dominating Central Traits, which in turn are more strongly asserted than Secondary Traits. A Cardinal Trait is a major motivator of behavior, and shapes the desired trajectory of an individual's life. These traits are more

rarely evidenced than those that are Central or Secondary, but when present are unmistakable. A businessman who is driven by a need to dominate his field and aggressively pursues hostile takeovers or an actress who absolutely needs to be loved by millions are examples of individuals shaped by a Cardinal Trait. These traits influence nearly every aspect of the individual's personality and behavior, and are clearly seen by others. The motivational power these traits possess is fearsome and unidirectional, capable of inspiring near compulsive behavior and rendering the description of an individual into such succinct and complete phrases as "a greedy man." Central Traits are present in every individual and are much more complex than Cardinal Traits, as they operate in concert with other Central Traits and Secondary Traits in shaping behavior. The relative strength of a Central Trait is influenced by the current environment to some degree, but are never totally repressed and rarely dominate other traits completely. Agreeableness, honesty, and trustworthiness are example of Central Traits. A person who is honest is also many other things, to describe their personality using only the word honest would be an incomplete description of the individual. Central Traits are expressed across situations and time. An individual with a strong honest trait will not typically "turn off" their honesty, just as a very disagreeable individual will frequently be just as grouchy tomorrow as they were today. Secondary Traits, according to Gordon Allport, are traits that arise under certain circumstances and are more in a state of flux and may deviate from the individual's traits which lie higher in the hierarchy. Likes and dislikes are a form of Secondary Traits, and are more difficult to predict than Central Traits due to their specificity. Secondary Traits also account for many behaviors that appear to be a deviation from an individual's Central Traits, as a specific circumstance may prompt the expression of a Secondary Trait in direct response. For example, a very organized person may bring absolute ruin to their office when attempting to track and kill a spider which crawled across their desk. Their consistent neatness which is an expression of a Central Trait is disrupted by the expression of their Secondary Trait, a primal loathing of spiders (Allport & Odbert 1936).

Trait Expression

Gordon Allport's hierarchy of traits makes up the internal personality structure of an individual, and the expression of these traits through behaviors is dependent upon the environment in which the individual occupies. To rectify this dual nature of traits, Allport borrowed a concept from biology and referred to the internal structure as an individual's *Genotype* and the external forces which shaped trait expression as their *phenotype*. This constant interplay of internal and external forces allows for behaviors which at first seem to imperil the claim of consistent and constant traits, such as in the earlier spider example. Allport believed that traits could be used to explain motivations for behaviors in a general sense, to find the commonality between disparate motivators for behavior. Allport also believed that a behavior that deviated from what was expected was also a result of trait expression, but in response to an external stimulus (Allport, 1931). Cardinal and Central Traits shape behavior in broad sweeping motions, the minutiae of everyday living cannot be ascribed wholly to the rigid traits which shape lifetimes but to the stimulus-response interactions governed by Secondary Traits. Furthermore, traits themselves are not rigidly ascribed an

immutable rank across individuals, but may exist at differing levels in different individuals. As an individual's phenotype is dependent upon the trait-environment interaction, an individual may possess traits that are contradictory and their expression determined by the situational circumstance (Allport, 1931). This allows for the complexity of an individual to be examined as the result of many competing forces, both internal and external.

Synonymous but Functionally Different

Allport strived to develop lists which included all manifestations of such underlying constructs, and felt that the expression of any one of these traits was sufficiently different from the others. Because of this sentiment, later work by others such as Raymond Cattell (see Cattell Trait Theory Lexical Analysis) drastically reduced the trait word lists by removing words deemed to be synonymous with existing traits, narrowing Allport and Odbert's list of 4,500 down to 171 (Cattell, 1943). The potentially overlapping nature of trait words was not seen as a problem for Gordon Allport, as he felt that our adjectives which are utilized to describe personality were touching upon a deeper construct. Allport intended to remove the moral implications of scientific trait words, espousing the value of developing a more rigorous and controlled language for research into personality traits. Honesty cannot ever be completely isolated from related traits such as trustworthiness and loyalty. Although these three traits are not completely overlapping and each adds functional value to a personality description, each trait has a different moral and societal implication, which impacts the ability to accurately assess their presence.

From his delineation of trait words and conceptualizations of trait expression, the lexical work which gave the field a common list of trait names to his behavioral motivation theories, Gordon Allport developed both a common language of study and a more rigorous roadmap for inquiry into personality traits. From his work decades of trait researchers expanded upon Allport's model and refined the nature of traits.

Whole Trait Theory

Kira O. McCabe

Vanderbilt University

Whole Trait Theory is an integration of personality and social psychology, serving as a new, combined theory (i.e. synthesis) from the person-situation debate. It outlines a process that explains how people can behave the same over time and also change in different situations.

The Person-Situation Debate

Whole Trait Theory emerged as a consequence of the person-situation debate. There were two camps to the person-situation debate that were diametrically opposed for decades. Situationist theorists asserted that people behave inconsonantly in different situations, stressing that this inconsistency means that situational contexts are vastly more important than an individual's personality. In contrast, trait theorists proposed that when you average across many situations, people do behave consistently, and personality traits are the best predictors of an individual's behavior. There was one fundamental question to resolve this debate: how could a single theory explain why people behave consistently most of the time and inconsistently in different situations?

Ultimately, both traits and situations are needed to explain what makes people different, how people differ, and why people differ. Whole Trait Theory was a new theory that combined the ideas of these two opposing sides. Rather than keeping traits and situations apart, Whole Trait Theory explained a process of how they can complement each other to explain behavior.

A New Approach to Traits

Traditionally, personality traits are measured once, in which a person reflects on his or her personality in general. People commonly reflect on behavior in different scenarios or whether certain adjectives describe how they normally think, feel, or behave. In contrast, a

density distribution of personality states (Fleeson, 2001) was a new approach to measuring traits. This personality measure is taken many times across a many different time points and situations. These repeated measurements come together to make an individual bell curve for each trait, which is called a density distribution.

These short personality measurements are called personality states. Personality states are how people act, think, or feel in a given moment. The concept of states was commonly used in research on emotions, showing how people change their mood in different situations. However, the same idea of states can be applied to explain changes in personality. A personality state is the same measure as a personality trait, but it occurs over a shorter period of time. For example, a common way to measure trait extraversion is to ask people how sociable they are in general. As such, the way to measure a personality state is to ask people how sociable they are over a given time frame (e.g. 30 minutes or 2 hours).

By asking people about their personality states across different situations, a density distribution of each individual's personality states (or trait manifestations) can be formed. This distribution looks like a bell curve with most responses around someone's average trait level, but also some points on the extremes of the dimension that show an individual's changes in behavior. The main benefit of the density distributions approach is that it can be used to test both the ways people are different from each other (between-person differences) and the ways individuals change in different situations (within-person differences). Statistically, the mean level of a trait can be used to test how two people are different on average, but the standard deviation can be used to test how often the same person changes their behavior in different situations. People have different distributions from each other. Some people vary little across different situations (low standard deviation), and some people vary a lot across situations (high standard deviation). Also, like other trait measures, some people on average are higher or lower on a distribution (reflected by their distribution mean). For example, a person who is high on extraversion may often act sociable in social gatherings, but they also may be quiet while working in the office. Work has shown that the within-person variance is substantially higher than the between-person variance on personality states, and personality states can vary as much as emotions from moment to moment. In other words, people are inconsistent in their behavior in different situations, yet they are still consistent when the researcher averages across these situations (with average correlations around .80 from one week to the next).

Whole Trait Theory incorporates the density distributions approach into a broader model of personality. Whole Trait Theory proposes that there are two sides to a trait: a descriptive side and an explanatory side (Fleeson, 2012). The descriptive side is the density distribution of personality states, which describes how people actually behave. The explanatory side builds on Allport's definition of traits and the cognitive-affective processing system (CAPS) model that traits are comprised of links among social-cognitive mechanisms, which can include internal factors, environmental influences, goals, and situational contexts. Ultimately, the explanatory side of traits functions to explain the descriptive side of traits.

Both the explanatory side and the descriptive side are two distinct sides of the same trait, which come together to form the "whole trait." These two sides can be viewed as two sides of the same coin – both sides must exist for the coin to exist. Yet each side is distinct because they are measuring two different things. While these two sides are independent from each other, there is a clear, causal relationship between the two sides – the explanatory side causes the descriptive side of states. As such, one side cannot exist in isolation of the other side.

Measuring Whole Traits

To measure whole traits, researchers need to measure the density distribution of personality states for each participant. Even though the explanatory side of traits incorporates social-cognitive mechanisms in its definition, traditional measures of personality traits can be used to measure the explanatory side of traits. For the descriptive side, personality state measure must be used to capture the descriptive side of traits. Common practice is to use personality adjectives in trait and state sentences to allow a direct comparison between the two measures (Fleeson, 2001). For example, the adjective "assertive" is a common extraversion item in personality scales. The item "How assertive are you in general?" can be used to measure the explanatory side of traits, while the item "How assertive were you in the last 30 minutes?" can be used to measure the descriptive side of traits. The same self-report scale can be used for both scales (i.e. answering each item on a 1–7 scale), which makes it easier to compare the explanatory side with the descriptive side.

Personality states are best measured through experience-sampling methodology (ESM), which has evolved over the past few decades from beeper and pager methods, to personal digital assistants (PDAs), to the present use of internet surveys on smartphones. Participants are instructed to complete the same short survey of personality states multiple times a day for several days (e.g. 5 times a day for 10–14 days). Participants should complete enough reports to capture both the stability and variability in personality across many different situations in their everyday lives.

Integrated Personality and Situation Process

Whole Trait Theory proposes that traits have two sides, and thus two separate numerical values for a trait. While these two sides generally have strong correlations with each other, the explanatory side may not always match descriptive side of the trait. People shift in their personality states regularly, similar to changing emotions. These changes can be explained to some extent by the explanatory side's social-cognitive mechanisms, which include situational, motivational, and cognitive influences. The explanatory and descriptive sides of traits are connected through these various mechanisms, which are integrative processes to explain people's actual behavior. Specifically, researchers using Whole Trait Theory try to explain how and why personality is stable and is variable across contexts by exploring the mechanisms between the explanatory and descriptive side of traits.

There are many social-cognitive mechanisms that have been and could be incorporated into Whole Trait Theory. These influences can be internal cognitions (e.g. motives or values) or external situational factors.

Situational

There are factors within a situational context that may help explain how or why people change their personality in a given moment. These contexts can be different environments – such as school, work, social, sport, and so on. It also may include certain situational cues or characteristics that influences an individual's personality state. For example, a boring situation may cause someone to engage in more (or less)

extraverted behavior. Other theories have proposed how situation characteristics may trigger certain cognitive-affective units of behavior (e.g. the CAPS model, DIAMONDS, etc.). However, the key difference is that Whole Trait Theory includes the structure of the Big Five to organize these meaningful differences. Still, existing theories and findings are not completely incompatible with the ideas presented in Whole Trait Theory.

Motivational

Research has shown increasing evidence that there is a strong relationship between the goals people are pursing and their personality states. Momentary goals predicted a large amount of fluctuations in state extraversion and state conscientiousness (50–75%; McCabe & Fleeson, 2012, 2016). Additional work showed that there are different goals for extraversion and conscientiousness, indicating goals can be mechanisms for personality states only if the personality state is relevant to the pursuit of the goal. For example, people trying to have fun were more extraverted, while people who were trying to get work done were more conscientious. Moreover, experimental work showed that goals cause changes in personality states. There is evidence that these goal-state relationships are also found with observer reports and are not limited to self-report.

Additional Constructs

Whole Trait Theory has proposed additional social-cognitive mechanisms that could be included as mechanisms to explain behavior. These mechanisms include narratives, values, beliefs, attitudes, competencies, expectancies, and others. Existing concepts, theories, and findings in social psychology also can be applied within this model as possible mechanisms to explain the descriptive side of traits.

Comparisons to Other Theories

Whole Trait Theory is compatible with other personality theories. It builds on existing trait theory, with the Big Five model of personality as its focal point. It serves to explain how and why the Big Five exists, as well as identify the specific functions of personality traits. Prior to Whole Trait Theory, trait theory was limited, merely describing differences between people that were important predictors of major life outcomes. A common critique of trait theory was that it describes who people are, but traits could not explain how or why people do what they do. Whole Trait Theory serves to enhance existing trait theories, by integrating processes into the ways in which personality is expressed in everyday life. Moreover, Whole Trait Theory can use the rich findings from existing Big Five research by applying trait-outcome relationships to momentary trait-state relationships. For example, research has shown the relationship between state extraversion and state positive affect, building on the work between trait extraversion and trait positive affect.

Moreover, Whole Trait Theory includes motivational and cognitive concepts within the domain of personality. Other theories (e.g. Five-Factor Theory, Neo-Socioanalytic Model, etc.) keep these concepts separate, and often view motivational and cognitive concepts as

outcomes of personality traits. Whole Trait Theory flips the direction of causality – these cognitive-motivational mechanisms cause personality states, which ultimately reflect the descriptive side of a personality trait. Ultimately, Whole Trait Theory is inclusive, uniting advances from personality, social, cognitive, and motivational perspectives in psychology.

Contributor Biographies

Natalie Abraham is a graduate from Spring Hill College. She earned her Bachelor of Science degree in psychology with a double minor in philosophy and health sciences. She plans to pursue a career in occupational therapy.

Stephanie L. Albertson is an assistant professor of criminology and criminal justice at Indiana University Southeast. Her research is interdisciplinary in the areas of criminology, criminal justice, and psychology. She has conducted research on the Chicago drug courts, community policing, and multi-jurisdictional task units. Her primary research focus is jury decision-making, capital jurors, and jury reform.

Mathias Allemand, PhD, is an assistant professor at the Department of Psychology and at the University Research Priority Program "Dynamics of Healthy Aging" of the University of Zurich. He directs a research group on personality dynamics and development across the lifespan. His primary interest lies in the understanding of the longitudinal patterns, mechanisms, and outcomes of personality change, dynamics, and development.

Catherine P. Allen is a PhD student in counseling psychology at the University of Central Arkansas. Her research interest is reducing recidivism in criminal populations with personality disorders.

Evan J. Anderson received his MS in counseling psychology from the University of Central Arkansas. He is currently a psychology instructor at the University of Central Arkansas in Conway, AR. Presently, he is co-developing a 12-week mentorship program for delinquent adolescents and serves within the Crime, Career, and Corrections Laboratory as a quantitative data analysis consultant.

Jennifer Andrews is an undergraduate student within the Department of Psychology at Central Washington University.

Damaris Aschwanden, PhD, is a postdoctoral researcher at the Department of Geriatrics in the College of Medicine at Florida State University. Her research focuses on the links between personality, cognitive abilities, dementia, and health.

Andrea L. Barbian-Shimberg is a professor in the Master of Arts in Professional Counseling program at the Liberty University in Lynchburg, Virginia, as well as, an adjunct

professor in the Master of Arts in Professional Counseling program at the University of the Cumberlands in Williamsburg, Kentucky. In addition to her responsibilities as an educator, Dr. Barbian-Shimberg maintains a private counseling practice in Huntersville, North Carolina where she specializes in the treatment of eating disorders.

A. Alexander Beaujean is an associate professor of psychology and neuroscience at Baylor University and a Fellow of the American Academy of Assessment Psychology. His research interests include the study of individual differences, especially the structure and measurement of human cognitive ability. He is the author of *Latent Variable Modeling in R: A Step-By-Step Guide* (2014, Routledge) and co-authored with John Loehlin the fifth edition of *Latent Variable Models: An Introduction to Factor, Path, and Structural Equation Analysis* (2017, Routledge).

Emorie D. Beck is a doctoral student in the Department of Psychological and Brain Sciences, Washington University in St. Louis, USA. Her interests include the application of network science to personality structure and architecture.

Jacob Belkin (MBA, Shenandoah University, 2017) is currently a community-based counselor with the National Counseling Group and is pursuing a Master's in clinical counseling.

Sara Bender is an assistant professor in the Department of Psychology at Central Washington University. She teaches a variety of undergraduate psychology and graduate counselor education courses, including courses in personality. Her research interests include the provision of mental health services to underserved populations, clinical supervision, and online supervision.

Arlin James Benjamin, Jr. earned his PhD in social psychology from the University of Missouri–Columbia in 2000. He is currently an associate professor in the Department of Behavioral Sciences at the University of Arkansas–Fort Smith. His primary research interests include the effects of aggression-related situational cues (e.g. violent video games, weapon images) on aggressive cognitions, behaviors, and aggression-related attitudes, as well as individual differences predicting aggressive behavior and attitudes toward violence.

Betsy Blackard is a graduate student at Claremont Graduate University. Her research interests include parent-child attachment and romantic relationships in adulthood.

A. Nayena Blankson (PhD, University of Southern California, 2007) is an associate professor of psychology at Spelman College. Her research interests include examining the links between cognitive skills, child characteristics, environmental conditions, and early achievement in children. She also has expertise in the use of rigorous quantitative methodology to address substantive research questions, including multilevel modeling, measurement invariance. structural equation modeling, and moderated mediation. She has authored over 20 peer-reviewed articles.

Cady Block, PhD, is an assistant professor, and research director of the Neuropsychology Clinic in the Department of Psychiatry and Behavioral Health at the Ohio State University. She holds concurrent appointments in the Departments of Neurology and Neurosurgery. Her research is in neuropsychological assessment of epilepsy, multiple

sclerosis, movement disorders, brain injury, and chronic pain. She is involved in national leadership, with positions in the Society for Clinical Neuropsychology, the International Neuropsychological Society, and the American Academy of Clinical Neuropsychology. She is a recipient of the Early Career Award (National Academy of Neuropsychology) and Young Investigator Award (American Pain Society).

Reneé R. Boburka (PhD, Pennsylvania State University) is a professor of psychology at East Stroudsburg University, Pennsylvania. Her current research interests focus on issues related to stereotyping and also teaching and learning. She has publications dealing with topics such as social cognition and pedagogy in various journals, including *Basic and Applied Social Psychology, Memory, Studies in Continuing Education, PsycCRITIQUES, Psychology Learning & Teaching, Journal of Research in Music Education*, and the *Sage Encyclopedia of Abnormal and Clinical Psychology*. She has also been a contributing author on several book chapters.

Sameen Boparai, BA, is a clinical psychology doctoral student at the University of Washington. She was previously a laboratory coordinator at the Health, Relationships and Intervention Laboratory at the University of California, Irvine. She recently co-authored a paper titled "Interaction between the opioid receptor OPRM1 gene and mother-child language style matching prospectively predicts children's separation anxiety symptoms." Her research interests include developmental psychopathology and emotion socialization.

Jessica L. Borelli, PhD, is an associate professor of psychology and social behavior at the University of California, Irvine. She is a clinical psychologist specializing in the field of developmental psychopathology; her research focuses on the links between close relationships, emotions, health, and development, with a particular focus on risk for anxiety and depression. Recent journal articles include: "Shedding light on the specificity of school-aged children's attachment narratives"; "Mother-child language style matching predicts children's and mothers' emotion reactivity"; "Reflective functioning in parents of school-aged children."

Laura Boxley, PhD, is an assistant professor, and training director of the Neuropsychology Clinic in the Department of Psychiatry and Behavioral Health at the Ohio State University. She holds concurrent appointments in the Departments of Neurology and Psychology. Her research is in the neuropsychological assessment of postconcussive disorder. She is involved in national leadership, holding a position within the Membership Committee within the Society for Clinical Neuropsychology.

April L. Brown, MPH, is a graduate of Spelman College (class of 2009) and current doctoral student of clinical psychology at Emory University. April is a former Gates Millennium Scholar and was recently awarded the Emory Graduate Diversity Fellowship – a highly prestigious entering student fellowship that is given to six or more students. She is a budding researcher in the Biosocial Underpinnings in Learning and Development (BUILD) Laboratory, where she studies the association between psychosocial stress and child psychopathology via hormonal processes within the neuroendocrine system.

Kathryn Bruzios (MS, Rivier University, 2015) is a clinical researcher at the University of Massachusetts Medical School and is appointed to the Department of Veterans Affairs. Her research interests include prevention science, underprivileged populations, and co-occurring

disorders. Her current research uses a multicomponent intervention with individuals who have a co-occurring mental illness and substance use disorder, and are homeless, amongst other factors.

Chelsey Bull is currently a student in the MS Mental Health Counseling program at the University of Central Arkansas. Her clinical and research interests include counseling Eastern cultures and working with juveniles in the criminal justice population.

Turhan Canli is a full professor of psychology and psychiatry, and founder/director of the Social, Cognitive, and Affective Neuroscience (SCAN) Center, and the Mind/Brain Center on War and Humanity at Stony Brook University and a fellow of the Association for Psychological Science. His research interests intersect psychology, neuroscience, and molecular biology with regard to individual differences in emotion, personality, social cognition, and mental health; neuroethics; and clinical/humanitarian outreach, research, education, and policy applications to global mental health and human rights.

Bernardo J. Carducci, PhD, was a full professor of psychology and director of the Shyness Research Institute (www.ius.edu/shyness) at Indiana University Southeast and a Fellow of the American Psychological Association in Divisions 1 (General Psychology), 2 (Teaching of Psychology), and 52 (International Psychology) and author of *The Psychology of Personality: Viewpoints, Research, and Applications* (3rd ed., 2015, Wiley).

Daniel Cervone is professor of psychology at the University of Illinois at Chicago. His interests include social-cognitive models of personality architecture and coherence. He is author of *Psychology: The Science of Person, Mind, and Brain* (2015, Worth Publishers/Macmillan), *Personality: Theory and Research* (co-authored with L. A. Pervin, 2016, Wiley), and *Personality: Determinants, Dynamics, and Potentials* (with G. V. Caprara, 2000, Cambridge University Press).

Cory L. Cobb is a PhD student in counseling psychology and research assistant at the Department of Psychology and Counseling, University of Central Arkansas. He has published multiple articles on undocumented Hispanic immigrants with respect to their coping strategies, acculturation experiences, and psychosocial functioning. Other research interests include factors that contribute to a positive research training environment among psychology students in doctoral programs.

Tyler L. Collette (MSm Texas A&M University–Kingsville, 2016) is a lecturer in the Department of Psychology and Sociology at Texas A&M–Kingsville, He received his BA degree in anthropology from the University of Texas-San Antonio. His previous research has examined cross-cultural differences in moral decision-making, children's preferences for morality stories, anti-fat attitudes, preferences for new group members, and the distribution of ethnic restaurants related to the ethnic composition of towns and cities across the United States. His research has been presented at the third Mediterranean Interdisciplinary Forum on Social Sciences and Humanities, Barcelona, Spain, and the International Convention of Psychological Science, Amsterdam, the Netherlands.

David M. Condon is an assistant professor in the Department of Medical Social Sciences in the Feinberg School of Medicine at Northwestern University. He received his BS from Duke

University, an MBA from the University of Chicago, and his PhD from Northwestern. His research program explores the predictive utility of individual differences in personality, cognitive abilities, and demographics. This work includes the development of assessment tools and prediction models that integrate the prominent domains of individual differences. His research has been supported by the Templeton Foundation through the Imagination Institute, the National Institutes of Health, and the National Science Foundation.

Alisha Conover is a research assistant with the Health, Relationships, and Interventions Laboratory (http://faculty.sites.uci.edu/thrivelab/) under the direction of Dr. Jessica Borelli at University of California, Irvine. Her research interests include examining the development of children's and adolescents' emotions and theory of mind through their attachment behaviors and social interactions.

Philip J. Corr is professor of psychology at City, University of London, UK. His research interests are in the general area of personality neuroscience, specifically individual differences in fundamental systems of emotion and motivation that underlie approach and avoidance behavior, and their conflict. In addition to extending this perspective to applied fields (e.g. occupational performance and behavioral economics), this research is especially important in the understanding of morbidity in clinical disorders – for example, McNaughton, N. & Corr, P. J. (2016). Mechanisms of comorbidity, continuity, and discontinuity in anxiety-related disorders. *Development and Psychopathology*, 28, 1053–1069. Further information: www.philipcorr.net

Kimberly B. Dasch-Yee, PhD, is an associate professor of psychology at Holy Family University. Her research interests focus on stress and coping in a number of populations, including college students, cancer patients, and among those who have experienced involuntary pregnancy loss. Her teaching interests include abnormal psychology, development, statistics, and research methods. Dr. Dasch-Yee earned her MA in psychology and PhD in clinical psychology from the University of Delaware and her BA in psychology from the University of Pennsylvania.

Hiten P. Dave is a PhD candidate in the Personality and Measurement program at Western University under the supervision of Dr. Donald H. Saklofske. He works with large datasets such as Statistics Canada's National Longitudinal Survey of Children and Youth (NLSCY), the interRAI 0-3 project, and the Trent Academic Success and Wellness Project. His research interests range from psychometrics and test construction to emotional intelligence, alexithymia, and mental health.

Ellie David is a first year PhD student in the Counseling Psychology PhD program at the University of Central Arkansas. His research interests include forensics and social justice topics.

Erica Dawson, PhD, is an assistant professor, and clinical director of the Neuropsychology Clinic in the Department of Psychiatry and Behavioral Health at the Ohio State University. She holds concurrent appointments in the Departments of Neurology and Psychology. Her research is in the neuropsychological assessment of brain tumors. She is involved in national leadership, with positions in the Early Career Committee and Award Committee within the Society for Clinical Neuropsychology.

Amber de Vere (MA, University of Southern Mississippi) is a PhD candidate in the Marine Mammal Behavior and Cognition Laboratory at the University of Southern Mississippi. Her research interests include marine mammal personality, emotions, and welfare, and conservation psychology.

Elvis DeFreese is a graduate counseling student at East Texas Baptist University. His research interests include integration of faith into counseling and the psychology of religion.

Eros R. DeSouza earned his PhD in community psychology from the University of Missouri at Kansas City. He is currently a professor of psychology at Illinois State University, where he regularly teaches both undergraduate and graduate courses on personality and history of psychology. Current areas of research include studies on social exclusion, prejudice, and discrimination.

Caitlin Dzikon (PhD, University of North Dakota, 2009) is an assistant professor of health psychology at Bastyr University where she teaches a variety of courses including personality psychology and psychological testing. She is a member of the Western Psychological Association and the Society for the Teaching of Psychology. Her clinical work focuses on blind rehabilitation and neuropsychological assessment. She has used the Wechsler Memory Scale, in conjunction with many other tests, to help patients with traumatic brain injury, MS, age-related cognitive decline, and the like, to improve and manage their health by understanding their cognitive strengths and weaknesses.

Larissa-Jayne Edwards (PhD, University of Akron, 2019) is a graduate psychologist within the Veterans Affairs Healthcare System. She has interests in both trauma and diversity issues and has both presented and published related to these topics at conferences, such as the American Psychological Association annual conference, and in the journal *Child Abuse and Neglect*.

Amanda ElBassiouny received her PhD in social psychology from Howard University. Her research focuses on the differences between religious, moral, and spiritual identities on various psychological and behavioral outcomes, including stereotyping, jury decision-making, cognitive functioning, personality variables, anxiety, and depression.

Lorien G. Elleman is a PhD student at Northwestern University in the Personality and Health Psychology program. His research interests are focused on maximizing effects by exploring different levels of personality – for example, finding the geographical unit by which individual personalities are optimally clustered, and improving the prediction of important life outcomes by using facets or items instead of broad traits. Prior to enrollment at Northwestern, Lorien was a credit risk analyst at the Federal National Mortgage Association.

Kara Eversole, BS, is a graduate of Denison University in Granville, Ohio. She is currently a neuropsychological psychometrician in the Department of Psychiatry and Behavioral Health at The Ohio State University College of Medicine. She is involved in face-to-face assessment of adults with a range of presenting clinical diagnoses including epilepsy, demyelinating conditions, movement disorders, dementia, and brain injury. She is also involved in research, managing the clinic's longitudinal dataset. She is looking forward to attending graduate school to achieve her long-term goal of becoming a board-certified clinical neuropsychologist in an academic medical center.

F. R. Ferraro (PhD, University of Kansas, 1989) is a Chester Fritz distinguished professor of psychology at the University of North Dakota, where he has been since 1992. From 1989–1992 he was a postdoctoral fellow at the Psychology Department and the Alzheimer's Disease Research Center at Washington University on St. Louis. He is also a fellow of the National Academy of Neuropsychology. He currently serves as editor-in-chief for *Current Psychology* and has also served as editor for both the *Journal of Psychology* and the *Journal of General Psychology*. His research is in the broad areas of cognitive aging, neuropsychology, information processing and human factors and he has over 250 publications and over 300 presentations. He recently edited and published the second edition of *Minority and Cross-Cultural Aspects of Neuropsychological Assessment – Enduring and Emerging Trends*.

Leia Friedman (MS, Rivier University, 2015) currently conducts research on the therapeutic effects of indigenous entheogenic plant traditions for individuals from industrialized cultures. Leia co-moderates an integrative and networking group called the Boston Entheogenic Network utilizing a harm reduction and cognitive liberty model.

Dallas R. Funk is a freelance writer and editor with 10 years' experience. She has sold seven children's stories, was selected for a short-story anthology, and was chosen as a featured writer in the second annual Art and Words show in Fort Worth, Texas. She is the former genre editor for the *Stonecoast Review* literary magazine and has an MFA in creative writing.

Zhipeng Gao holds a PhD in psychology from York University and is currently a SSHRC postdoctoral fellow at Simon Fraser University. He studies the history and theory of psychology with focuses on how psychologists' research questions, assumptions, and methods are informed by social and cultural factors. In addition, he studies China's moral ideals, social deviance, and nationalism. His select publications can be found in *Review of General Psychology*, *History of Psychology*, *Annual Review of Critical Psychology*, *The Praeger Handbook of Social Justice and Psychology*, *History of Science*, and *Social Anthropology*. More information about Zhipeng Gao's research is available at: https://sites.google.com/view/zhipenggao.

Gerin E. Gaskin, is an advanced graduate student at Claremont Graduate University and a research assistant at the CARE Laboratory at Pomona College and at the THRIVE Laboratory at the University of California, Irvine. She is a psychological assistant at emPATH Clinical. Her research interests include exploring best practices to support parents of children with autism, and assessing experimental interventions for vulnerable populations. Recent publications include: *Children's and Parents' Perceptions of Vulnerability as Weakness: Associations with Children's Well-being; School-aged children's Cognitive Interdependence as a Prospective Link Between their Depressive Symptoms and Physiological Stress Reactivity*.

Aaliyah Gibbons is currently pursuing a Doctorate of Psychology in clinical psychology. Aaliyah completed her undergraduate studies in biology and interdisciplinary social science at Clarkson University. During her undergraduate career, she did research on peer victimization and mental health in the Social Development and Health Psychology

Laboratory. She has also presented oral and poster presentations both regionally and internationally. Aaliyah plans to become a correctional facility psychologist in the future.

Amber Gibson (BSW, Stephen F. Austin University, 2011) is an advanced doctoral student in the school psychology program at Howard University.

Lewis R. Goldberg is a senior scientist at the Oregon Research Institute and an emeritus professor of psychology at the University of Oregon. Among his honors are the Jack Block Award for outstanding career contributions to personality research from the Society of Personality and Social Psychology, the Saul Sells Award for outstanding career contributions to multivariate research from the Society of Multivariate Experimental Psychology, and the Bruno Klopfer Award for outstanding lifetime contributions to personality assessment from the Society of Personality Assessment. His contributions to the scientific literature in personality and psychological assessment have included articles on judgment and decision-making, and the development of taxonomies of personality-descriptive terms in diverse languages. To provide public-domain measures of the most important personality attributes, he has developed an Internet-based scientific collaboratory, the International Personality Item Pool (IPIP: http://ipip.ori.org/).

Christina Graziano earned her MS in experimental psychology from Rivier University, during which time she conducted an original thesis entitled "Social source monitoring: Tweeting your way to academic success," examining the relationship between social networking and source monitoring in recognition memory. She is currently working toward a PsyD in school psychology and counseling while working for a homeless outreach program.

Andrea E. Grünenfelder-Steiger, PhD, is a research associate at the Institut Neumünster, Switzerland. Her research interests are centered around self and personality development across the whole lifespan, from late childhood into very old age. In her current work, she mainly focuses on how self-esteem and other aspects of personality can be positively influenced in individuals' everyday life.

Sarah E. Hampson, PhD, is a senior scientist at the Oregon Research Institute. She studies personality and health over the lifespan. Originally from the UK, she held academic appointments at the University of Lancaster, Birkbeck, University of London, and the University of Surrey before moving to Oregon. She is a past-president of the European Association of Personality Psychology. In her research, she examines the influence of personality traits on health behaviors and health status at various stages of the life course from infancy to old age.

Elizabeth Harwood (PhD, University of Montana, 2008) is an assistant professor and department co-ordinator of psychology at Rivier University. The 2016 recipient of the NH Excellence in Education Award for Outstanding Teaching in Postsecondary Education, Dr. Harwood's research interests range from the best practices in the teaching of psychology to predictors of mental health in college students.

José M. Hernández is an associate professor of psychology in the Department of Biological and Health Psychology at the Universidad Autónoma de Madrid. He is an experienced teacher and researcher on personality psychology.

Patrick L. Hill, PhD, is an associate professor at the Department of Psychological and Brain Sciences of the Washington University in St. Louis. His research focuses on understanding how individuals develop a sense of purpose in life, personality change in adolescence and adulthood, as well as associations between individual differences and healthy lifestyle factors.

Kajung Hong, BA, is a doctoral student at SDSU/UC San Diego Joint Doctoral Program in Clinical Psychology and former laboratory manager at the Health, Relationships and Intervention Laboratory at the University of California, Irvine. She co-authored a research paper, "Reflective functioning, physiological reactivity, and overcontrol in mothers: Links with school-aged children's reflective functioning" (Borelli, Hong, Rasmussen, & Smiley, 2017). Her research interests include child maltreatment, parent-child relationship, and clinical interventions.

Amy Hufstedler is a student in the Counseling Psychology PhD program at the University of Central Arkansas. Research interests include strategies for counseling current and former military service members and human-animal interactions.

Linda M. Isbell is a full professor in the Department of Psychological and Brain Sciences at the University of Massachusetts Amherst. Her research investigates the joint influence of affective and cognitive factors on social information processing in a wide variety of domains, including impression formation, the self, politics, and medical decision-making. She is an author of "The affective control of thought: Malleable, not fixed," in *Psychological Review* (Huntsinger, Isbell, & Clore, 2014), as well as many other articles that provide empirical support for the notion that affective experiences serve as information that guides individuals' thoughts, judgments, and actions.

De'Lon Isom (BS, Texas A&M University, 2011) is a doctoral candidate in the school psychology program at Howard University.

Priya A. Iyer-Eimerbrink is an assistant professor in the Psychology Department at the University of North Texas at Dallas. She earned her BA at Purdue University, MS, and PhD at the University of Texas at Arlington and completed a postdoctoral position at Indiana University School of Medicine. Her current research interest focuses on why some children may be more adversely affected by peer victimization than other children. Her program of research takes a multidisciplinary approach and is founded on the framework that peer victimization is a stressful life event capable of detrimentally altering an individual's biological functioning and mental health.

Meryl Jacob is an MBA student at the University of Texas at Dallas. She completed her undergraduate degree in neuroscience with a minor in psychology. She is currently working on a business degree with a concentration in healthcare management in hopes of pursuing a career to increase access and quality of care for behavioral health patients.

Feng Ji received his Master's in quantitative psychology from Illinois State University. His research interests include online research methods, item response theory, and Bayesian statistics.

Laura K. Johnson is a PhD candidate in the Personality and Measurement program at Western University under the supervision of Dr. Donald H. Saklofske. Her research

interests include the assessment of prosocial traits (e.g. altruism, compassion, empathy) and antisocial personality traits (e.g. the Dark Triad, sadism).

James Kean is research fellow at Monash Institute of Cognitive and Clinical Neurosciences (MICCN) and leads a team of researchers investigating all aspects of attention in children (aged 3 to 6). He is also an associate investigator at the Centre for Human Psychopharmacology, directed by Professor Con Stough, at Swinburne University of Technology since 2014. He earned a Bachelor of Science in psychology in 2008 at Deakin University, Melbourne, and an Honors Degree in psychophysiology in 2009, at Swinburne University of Technology. He is currently earning a Doctorate of Philosophy in Science (Neuropharmacology), with a specific focus on child and adolescent neuroscience and complementary alternative medicine research. His work has been published in a number of international journals including *Psychopharmacology, Frontiers in Pharmacology, Phytotherapy Research, Complementary Therapies in Medicine, Nutrients, Nutrition Journal,* and *Journal of Alternative and Complementary Medicine.*

Lucas A. Keefer (PhD, University of Kansas, 2014) is an assistant professor at the University of Southern Mississippi. His research interests include attachment, existential, and political psychology.

Margaret L. Kerr is an assistant professor of human development and family studies at the University of Wisconsin–Madison. Her research focuses on attachment and emotional experiences in parent-child relationships, with a distinct focus on the emotional experiences of parents of young children. Her research has used LIWC to examine how parents think about and discuss their parenting experiences and parent-child relationships.

Scott P. King (PhD, social psychology, Loyola University Chicago, 2010) is a professor of psychology at Shenandoah University. His research specialties include generational dynamics, measurement validity, psychology pedagogy, and the intersection of social media and personality. His most recent publication, "#worthit? Integrating Twitter into Introductory Psychology Curriculum" appeared in the edited volume *The Use of Technology in Teaching and Learning* in 2018.

Jennifer M. Knack, currently associate professor of psychology at Clarkson University, completed her undergraduate studies at Saint Bonaventure University, graduate studies at the University of Texas at Arlington, and postdoctoral fellowship at the University of Ottawa. Jennifer runs the Social Development and Health Research Laboratory at Clarkson and is Mentoring Director for a program pairing college mentors with high school students. She examines how negative social experiences and social stressors such as being bullied impact health and well-being. She is interested in how people detect traces of others' mental health status on social media and decide when to offer help.

Laura B. Koenig, PhD, is currently an assistant professor at Winona State University. She teaches courses in personality, research methods, and behavior genetics. Her research interests include the development of and genetic and environmental influences on religiousness, spirituality, and personality. Her publications include studies on the heritability of religiousness in adolescence and adulthood, the change and stability in religiousness and spirituality through the transition to emerging adulthood, and the relationships between religiousness, personality, and alcohol use.

Elicia C. Lair is a limited term assistant professor in the Psychology Department at Kennesaw State University. Her research interests include affect and cognition, information processing styles, individual differences, and social cognition more broadly. Recently published work in *Personality and Social Psychology Bulletin* by Linda Isbell, Elicia Lair, and Daniel Rovenpor in 2016, entitled *The impact of affect on out-group judgments depends on dominant information-processing styles: Evidence from incidental and integral affect paradigms* demonstrates how affect provides feedback about cognition to influence judgments of out-group members and behavioral intentions toward them.

Lauren M. Littlefield (PhD, Drexel University, 1997) serves as professor and co-ordinator of the Clinical/Counseling and Psychology Internship programs at Washington College. She is a practicing clinical psychologist with a specialization in neuropsychology. Publishing in the areas of multi-tasking, self-regulation and working memory capabilities, assessment of executive functioning is her primary research interest.

Shay Luu is currently working as a management analyst for the Mecklenburg County Department of Social Services. He graduated with a Master's in psychology from Howard University and his research interests are minority health disparities and spirituality. Shay has published research on minority health disparities in an indigenous sub-Saharan African population.

Heike Maas is a senior lecturer in the Department of Psychiatry of the Saarland University. She received her PhD in personality psychology focusing on questions regarding the etiology of individual differences. She is interested in the interplay of genes and environment and was involved in various German and Canadian twin studies, working together with Professor Alois Angleitner, Professor Rainer Riemann, Professor Frank M. Spinath, and Professor Kerry L. Jang. Recently her focus of interest shifted to factors influencing health and well-being in medical students and to clinical communication in health.

Cristina L. Magalhães (PhD, Nova Southeastern University, 2005) is professor of clinical psychology and associate director of the PsyD program at the California School of Professional Psychology at Alliant International University, Los Angeles. She is also a licensed clinical psychologist in independent practice. Dr. Magalhães' clinical, research, and teaching interests include psychodiagnostic and cross-cultural assessment; treatment approaches for anxiety and trauma-related disorders; and LGBTQ health.

Celeste M. Malone (PhD, Temple University, 2012) is an assistant professor and co-ordinator of the Howard University school psychology program. Her research interests include multicultural and diversity issues in the training and practice of school psychology.

Michael Patrick Mann (PhD, University of Missouri at Columbia) is a full professor and assistant chair of the Department of Psychology at Mississippi College. He earned his Master's degree in counseling psychology from Durham University in England and his PhD in counseling psychology from the University of Missouri in Columbia, Missouri. One of his research interests is non-verbal assessments of personality. He is the author or co-author of at least 15 journal articles and one book chapter.

Megan E. Mansfield received her Master's degree in applied social psychology and evaluation from Claremont Graduate University and is currently working on her PhD in applied social psychology under the advisement of Dr. Allen Omoto. Her research broadly

examines prosocial engagement and community building and bringing this work to inform program decisions and policies. She has worked on a variety of evaluations and applied research projects related to issues such as sexual and partner violence, community-based policing, and sexual minority service in the U.S. military.

Alexandros Maragakis (PhD in Clinical Psychology, University of Nevada, 2015) is an Assistant Professor of Psychology at the Eastern Michigan University. He has published numerous articles and book chapters that focus on the integration of primary and behavioral healthcare systems and the utility of quality improvement within those settings. His clinical work involves delivering integrated behavioral health services within federally qualified healthcare centers and community mental health clinics.

Annika A. Martin, PhD, is a project manager "Studium Digitale" at the Digital Society Initiative of the University of Zurich. Her research during her doctoral studies focused on personality development across adulthood and old age with a special focus on adult attachment processes.

Brittany A. Mason (MS, applied behavioral analysis, Shenandoah University, 2016; MS, psychology with an emphasis in forensic psychology, Grand Canyon University, 2019) is a board certified behavior analyst at Grafton Integrated Health Network.

Hannah Masoner earned her Bachelor of Science at Spring Hill College in Mobile, Alabama. She majored in psychology with an emphasis in biology.

Khairul Anwar Mastor is a professor of personality psychology, Head of Personality Research Group at the Center for Liberal Studies (CITRA) and Head of Heritage and Civil Society Research Cluster, Universiti Kebangsaan Malaysia (UKM), Bangi, Malaysia. His major research interests are personality structure and processes, personality and religiosity development and the application of Social Investment Theory (SIT) in the religious-personality relationships.

Vitoria Meira (MA Candidate, Claremont Graduate University) is a current graduate student of positive developmental psychology and evaluation at Claremont Graduate University. Her research focuses on how parental emotion-regulation and mindfulness influence the socio-emotional development and authenticity of children and adolescents.

Karen B. Meteyer, PhD, is an associate professor of psychology and director of the Clinical Psychology program at Rivier University as well as a Licensed Clinical Psychologist. Her research focuses on family dynamics, parenting and predictors of alcohol use and mental health among college students.

M. Justin Miller has been a research associate at the Shyness Research Institute, directed by Dr. Bernardo J. Carducci, at Indiana University Southeast since 2013. He earned a Bachelor of Science in psychology in 2014 and a Graduate Certificate in liberal studies in 2015, both at Indiana University Southeast. He is currently earning a Master of Science in applied psychology with concentrations in industrial/organizational psychology and evaluation research at the University of Wisconsin–Stout. At the University of Wisconsin–Stout, Miller is a research

assistant at the Applied Research Center and graduate assistant at the Graduate School. He has been published in *Scholarship of Teaching and Learning in Psychology* and *Indiana University Southeast Graduate Research Journal*.

Richard L. Miller (PhD, Northwestern University, 1975) is professor and chair of the Department of Psychology and Sociology at Texas A&M University–Kingsville. He is a fellow of the American Psychological Association and the Association for Psychological Science. He is a co-editor of *Social Comparison Processes,* STP e-books on undergraduate research, student engagement, and academic advising, and served as a section editor of *The Encyclopedia of Cross-cultural Psychology*. He is the recipient of the CASE United States Professor of the Year Award in 2009 and the 2012 Charles L. Brewer Distinguished Teaching of Psychology Award from the American Psychological Association.

Wenting Mu is a graduate student in clinical psychology at the University of Illinois at Urbana-Champaign.

Jason M. Murphy is a faculty member in the Department of Psychology at Southern Illinois University Edwardsville. He earned his PhD in clinical psychology with a specialization in neuropsychology from Saint Louis University in 2013. His current research focuses on the intersection of technology and psychological service delivery, including e-therapy consumer privacy, telepsychology training for graduate students, and informed consent for online psychotherapy.

Kate Myers is a junior undergraduate student in biology/pre-med at the University of Central Arkansas. Her research interests include physical chemistry, biochemistry, and behavioral science.

Lauren B. Nickel is a graduate student in personality psychology at the University of Illinois at Urbana-Champaign. Her research interests include the relationship between personality and health.

Gerald E. Nissley, Jr. is an associate professor of psychology at East Texas Baptist University. As a licensed psychologist, he maintains a private practice. His research interests include teaching of psychology and integration of faith into counseling. His most recent publications include: G. E. Nissley, (2016). Be strong and courageous: Faith-integrated adaptation of Trauma-Focused Cognitive Behavioral Therapy for support of child survivors of maltreatment. *Journal of Applied Christian Counseling, 1*(2), 15–17.

Jon Nolan is a second-year PhD student in the Counseling Psychology PhD program at the University of Central Arkansas. His research interests include mindfulness meditation, and integrated care. He is currently working on completing his dissertation regarding the use of mindfulness based mobile applications in the integrated care setting.

Jun Won Park is a doctoral student in organizational behavior in the School of Management at Yale University. His research focuses on understanding how multiple intersecting social identities shape how people think, act, and feel. He has conducted research in the areas of implicit social cognition, morality, social identity, social class, emotion, and impression formation.

Sonia Parker is a graduate student in educational psychology at Baylor University.

Kyle Z. Pasquariello graduated from Clarkson University with a double Bachelor of Science in psychology and biology. He worked in the Social Development and Health Psychology Research Laboratory studying the influences of social pain and pain memories on self-control and indirect aggression. During his undergraduate studies, Kyle presented his research at local, regional, national, and international conferences. Kyle also earned a Master's degree in psychology at SUNY University at Buffalo working in the Laboratory of Motivation and Addiction studying motivation and drug addictions.

Adam R. Pearson (PhD, Yale University, 2011) is an associate professor of psychology at Pomona College and a member of the graduate faculty at Claremont Graduate University. His research explores how people navigate diverse environments with a particular focus on understanding how non-conscious biases shape intergroup interaction, perception, and behavior. He is a recipient of an Early Career Achievement Award from the American Psychological Association, the Morton Deutsch Award from the International Society for Justice Research, and the Social Psychology Network's 2014 Action Teaching Award for innovative teaching. His research on contemporary racism has been cited in legal cases on affirmative action and in policy initiatives addressing biases in law enforcement.

Kristina C. Peterson, BS, is a research associate at the Indiana University Southeast Shyness Research Institute, a current student at Western Kentucky University in the Clinical Psychology Master's program, and a member of Psi Chi.

Matthew Peterson, BS, is a research associate at the Indiana University Southeast Shyness Research Institute and member of Psi Chi.

Karlye A. Phillips (BA, Spelman College, 2015) is a research assistant with the Veterans Affairs Medical Center in Atlanta, Georgia. Her research interests include examining co-occurring metabolic syndrome, anxiety, and stress related disorders to understand premature senescence. She is also interested in developmental and psychosocial consequences of trauma on children and families. She is currently working on a study that explores the effects of trauma-sensitive yoga as an alternative to psychotherapy on posttraumatic stress disorder, depression, and associated symptoms. Additionally, she has presented on posttraumatic stress disorder at several local and national conferences.

Jasmin Pizer graduated from Spring Hill College in Mobile, Alabama. She majored in psychology and minored in biology.

John F. Rauthmann is professor of personality psychology and psychological assessment at the University of Lübeck. He studied at the University of Innsbruck, earned his PhD at the Humboldt-University of Berlin, and worked as an assistant professor at the Wake Forest University. His interests lie in personality structure and processes; psychological situations (their conceptualization, taxonomization, and measurement); and person-situation transactions (e.g. how people perceive, navigate, and shape situations).

Stephanie B. Richman is an assistant professor of psychology at Baldwin Wallace University. She is a social psychologist whose specific research interests include relationships, social rejection, and the self-concept. She has authored such papers as "Reaching out

by changing what's within: Social exclusion increases self-concept malleability" which was published in the *Journal of Experimental Social Psychology*.

Josh Root, MS, is a graduate of the University of Central Arkansas's Mental Health Counseling program. His research interests include applications of behavioral and cognitive behavioral therapy.

Víctor Rubio is an associate professor of psychology in the Department of Biological and Health Psychology at the Universidad Autónoma de Madrid where he teaches behavior modification and psychological assessment. His research has focused on psychological assessment and health psychology.

José Santacreu is a professor of psychology in the Department of Biological and Health Psychology at the Universidad Autónoma de Madrid. He is a clinical psychologist who has had a long career in teaching and research on behavioral modification and health psychology.

Wilfred Santiago III graduated from Spring Hill College in Mobile, Alabama. He earned his Bachelor of Science degree in psychology with a double minor in philosophy and health sciences.

H. Russell Searight, PhD, MPH, is professor of psychology at Lake Superior State University in Sault Sainte Marie, Michigan. His areas of research and scholarly publication include the social history of personality and psychotherapy, clinical psychology and primary health care, emerging adulthood, and undergraduate psychology education.

Justin M. Shepherd (MS, Rivier University, 2015) is a clinical researcher in the Behavioral Psychopharmacology Research Laboratory at McLean Hospital. His research interests focus on the pharmacokinetics of alcohol and the neurobiology of cocaine and nicotine dependence.

Megan D. Shevenell (MS, Rivier University, 2015) has a Master of Science degree in clinical psychology from Rivier University. Her research interests include the study of gender and well-being in vulnerable populations, including emerging adults and clinical populations of adults with mental illness. She is a co-author on "Feasibility of behavioral weight loss treatment enhanced with peer support and mobile health technology for individuals with serious mental illness" in *Psychiatric Quarterly*.

Charity A. Smith (PhD, University of Akron, 2019) is postdoctoral therapist currently serving in the area of community mental health. She is a member of the American Psychological Association Division 17 (Society of Counseling Psychology), the Association for Death Education and Counseling, and the American Association of Suicidology. She holds a Masters degree in thanatology, and her interests center on death, dying, and bereavement; suicidology; LGBT-related concerns; and substance use disorder recovery. Her dissertation focused on the exploration of alcohol use disorder and perfectionism.

Tiffany Smith is an assistant professor of Psychology at the University of Wisconsin–Stout, where she teaches subjects such as research methodology and evaluation to both undergraduate and graduate students. She has a Bachelor's degree in psychology and philosophy

from the University of Tennessee, Knoxville and a doctoral degree in educational psychology with a concentration in evaluation, statistics, and measurement from the University of Tennessee as well. Her primary research interests include stakeholder communication and involvement as well as reflective practice in evaluation. She has been published in diverse journals such as the *Journal of Evaluation and Program Planning*, *To Improve the Academy*, *World Medical and Health Policy Journal*, *Postgraduate Medical Journal*, and the *British Journal of Sports Medicine.*

Susan Snyder has an MA in psychology from Washington College. Her area of study is creativity and how it relates to personality traits and identifying characteristics that may lead to the ability to predict creativity in individuals.

Lucas M. Sohn, BA, is a study co-ordinator at the Health, Relationships, and Intervention Laboratory at the University of California, Irvine. Recent publications: "School-aged children's attachment dismissal prospectively predicts divergence of their behavioral and self-reported anxiety"; "Therapist-client language matching: Initial promise as a measure of therapist-client relationship quality" (under review).

Lekeisha A. Sumner (PhD, Illinois Institute of Technology, 2006) is a licensed clinical psychologist with dual expertise in clinical and clinical health psychology. She has board certification in health psychology and is a fellow of the Academy of Clinical Health Psychologists. Dr. Sumner is a clinical faculty member in the Medical Psychology Assessment Center in the Department of Psychiatry and Biobehavioral Sciences at the University of California, Los Angeles (UCLA). She has worked in several capacities in academia, healthcare, and consulting.

Constance A. Sztukowski-Crowley is a recently retired professor of psychology and counseling and currently resides in Port St. Lucie, Florida. She was previously director of the undergraduate Psychology program and the graduate Counseling program at South University in Montgomery, Alabama. Dr. Sztukowski-Crowley is a member of the American Psychological Association in Divisions 1 (General Psychology), and 2 (Teaching of Psychology). Her primary research interest is the science of teaching and learning.

Thomas Valentine, MA, is a doctoral candidate in clinical psychology, with concentrations in health psychology and quantitative psychology, at the Ohio State University. His research interests include examining the intersection of cognition and emotion in chronic disease populations. He has received training in neuropsychological assessment and cognitive rehabilitation. Following completion of his doctoral degree and postdoctoral training, he plans to continue to embrace his passion for research, clinical work, and teaching via a career in clinical neuropsychology.

Femina P. Varghese is a tenured associate professor in the Counseling Psychology PhD program at the University of Central Arkansas. Her research interests include the career development of criminal justice populations and risk and protective factors in recidivism. She is currently serving as past-president of the American Psychological Association's Division 18 and is a past Chair of Division 18's Criminal Justice Section.

Arne Weigold (PhD, Texas Tech University, 2008) is an associate professor of psychology at Kent State University at Geauga. His areas of interest include data collection methodology, equivalence testing, assessment, and cross-cultural psychology. He has published articles

related to these topics in journals such as *Psychological Methods, Psychological Assessment, Computers in Human Behavior,* and *International Perspectives in Psychology*.

Ingrid K. Weigold (PhD, Texas Tech University, 2007) is a professor in the APA-accredited Counseling Psychology program at the University of Akron. She has interests in both scale assessment and international student adjustment and has published articles related to these topics in outlets such as *Assessment, Psychological Assessment*, *International Journal of Intercultural Relations,* and *International Perspectives in Psychology*.

Eric B. Weiser is a professor of psychology at Curry College, where he is chair of the Psychology Department. His research interests include social and personality psychology, psychopathology, social media, and multivariate statistics. He has published numerous peer-reviewed journal articles and chapters in psychology textbooks, and he has been called upon by local media to comment on matters relevant to psychology.

Jared Whitmire is a second-year MS student in the Mental Health Counseling program at the University of Central Arkansas. His research interests include exercise, well-being, and mental health interventions.

Joshua Wilt is a postdoctoral fellow in the Department of Psychological Sciences at Case Western Reserve University. His research is broadly concerned with investigating affective, behavioral, cognitive, and desire (ABCD) components that are relevant to personality structure and function. His current research examines ABCDs within the context of personality traits and life-story episodes.

Nicole Woodhouse is a graduate student at Baylor University in the School Psychology program.

Alanna Wormwood is a mental health worker in upstate New York. She graduated from Clarkson University in 2015 with Bachelor's degrees in psychology and history. During her undergraduate career she did extensive research in the Social Development and Health Psychology Laboratory on the topics of peer victimization, mental health, and cognitive processing. She has co-authored a chapter in *Bullying: Prevalence, Psychological Impacts, and Intervention Strategies* and presented oral and poster presentations on the subject regionally and nationally. She is completing a Master's degree in mental health counseling from Northwestern University.

Dong Xie (PhD in counseling psychology, Ohio State University, 2004) is an Associate Professor of Psychology at the Department of Psychology and Counseling, University of Central Arkansas. He is a licensed psychologist in state of Arkansas. He has a bachelor's degree and a master's degree in psychology from Peking University, Beijing, China. His research interests include cultural-specific personality correlates of emotional distress, personality assessment and its application in cross-cultural contexts, and multicultural counseling and development. He has been serving on the editorial board of the *Journal of Multicultural Counseling and Development* since 2009.

Jennifer N. Yuen, BA, RBT, is a research associate of the Health, Relationships, and Interventions Laboratory at the University of California, Irvine.

Theoretical and Methodological Issues in Personality Research

General Concerns and Considerations

Daniel Cervone[1] and Emorie D. Beck[2]

[1] *University of Illinois at Chicago*
[2] *Washington University in St. Louis*

Personality scientists can access an array of research methods that is exceptionally broad. In principle, breadth is advantageous; it enables researchers to select data-gathering tools that best fit their professional goals. In practice, however, wise selection can be challenging. A proper fit of methods to theoretical aims, and eventual empirical claims, requires attention to a set of conceptual considerations. These considerations bear not only on the choice of data-collection techniques, but also on the analysis and interpretation of the evidence they yield.

Three conceptual considerations stand out. *Pretheoretical* considerations constrain the conclusions that personality psychology may draw from data. *Theoretical* positions contain assumptions about the types that are required to assess personality structure, dispositions, person-situation interactions, and inter-individual differences. Finally, *pragmatic* concerns guide choices that one can make from among alternative data-collection tools.

Pretheoretical Constraints

Pretheoretical considerations are general principles of scientific logic and inference. We refer to them as "pretheoretical" because they developed outside of, and commonly prior to, theoretical developments in personality psychology, per se. The relevant principles generally come from philosophy (especially the philosophy of science), measurement theory, and statistics. No matter what one's theoretical orientation is, these are principles to which the personality scientist must adhere.

Although developed outside of the field, pretheoretical principles have compelling implications for personality research. In particular, they constrain the conclusions one may draw from various research designs and forms of data.

Constraints in the Study of Personality Development

The study of personality change across the life course provides a simple example of how pretheoretical principles constrain the selection and interpretation of research methods. The constraint arises when personality psychologists wish to determine whether a given personality quality changes systematically across the course of life.

When selecting a research design, statistical principles indicate that one simple design – a cross-sectional comparison of people of different ages with respect to the personality quality – is insufficient to yield unequivocal conclusions about change across the life course. At any given point in time, people of different ages represent different cohort groups who may have different sociohistorical experiences. A comparison of age groups thus confounds age of research participant with sociohistorical influences that may have affected one, but not another, cohort. This constraint underscores the importance of longitudinal methods, in which the same individuals are studied across extended time periods.

Constraints in Establishing Causality

A second example of pretheoretical constraints arises when the researcher's goal is to establish causality, that is, to determine whether a personality factor causally contributes to the occurrence of a behavioral outcome. In this case, the relevant pretheoretical constraints come from scholarship in the study of scientific explanation. Although different positions can be found in this field, a core principle is widely accepted: A minimal condition for establishing causality is to document whether a potential causal factor covaries with a given outcome. An extension of the covariation principle is the "manipulability" criterion of Woodward (2003), who explains that if one wishes to claim that a process causally contributes to observed outcome, then a manipulation of the process should produce a change in the outcome; the manipulated change, in other words, should covary with the outcome of interest.

These considerations raise three points that bear on research methodology. The first is the value of *experimental* personality research; as in any branch of the psychology, in personality psychology experimental methods are the tools of choice for establishing causality. The second is a warning about "third variables" when correlational methods are employed. An observed covariation between a personality quality and an outcome could reflect, at least in part, the influence of an unobserved third factor that covaries with the personality quality. For example, an observed correlation between openness to experience and academic outcomes could reflect the influence of fluid intelligence, which correlates with openness, on academic performance. Pretheoretical considerations constrain the personality psychologist from claiming that the correlated personality quality causally explains the outcome. The third point involves the choice not only of methods, but of theoretical constructs. Some personality constructs are conceived as fixed qualities; for example, personality traits identified in latent variable analyses of inter-individual differences are often viewed as essentially unchanging (or displaying only minimal change) once an individual reaches adulthood. For any given individual, then, these qualities are constants; the person's standing on the traits is fixed. As others have explained, since the traits are constants, they do not covary with any behavioral occurrences and thus cannot be invoked as causes of a behavioral outcome. Claiming

that a static disposition is the cause of a given person's actions (e.g. "Mary's high-level extraversion was the cause of her deciding to attend the party today") is simply not a theoretical option; scholarship outside of the field constrains the personality scientist from making that claim. The personality psychologist who wishes to determine the causal impact of personality qualities on social outcomes must attend to such constraints when developing theory and selecting research methods.

Constraints in the Study of Personality Architecture

A third goal for which the personality psychologist faces pretheoretical constraints is the identification and assessment of *personality architecture*, that is, the intra-individual organization and functioning of personality structures and dynamics. Theorists have provided models of personality architecture ever since the landmark work of Freud. Perhaps the major advance in personality theory since that time is the effort to ground theoretical models in objective scientific evidence.

When seeking such evidence, one faces a pretheoretical constraint that stems from a principle known as the "fallacy of division": If a statement correctly characterizes a population, it is fallacious to assume that the statement also characterizes each of the individuals in the population. Applied to the psychology of personality, this implies that statistical analyses of populations cannot be assumed to provide information about personality architecture at the individual level. For example, if a dimension such as generalized "agreeableness" emerges in analyses of inter-individual differences in the population, one cannot assume that each individual possesses a corresponding "agreeableness" mental structure. Making such an assumption is not a theoretical option; it is a violation of a pretheoretical constraint. Measurement theory, and associated computer simulations, document convincingly that intra-individual psychological tendencies may diverge markedly from inter-individual dimensions that are found in statistical analyses of the population as a whole.

The psychologist interested in intra-individual personality architecture thus must turn to intra-individual research methods. These may include experience sampling methods (see below) that provide intensive study of the individual case, or idiographic research strategies that employ laboratory-based measures (also see below) that yield detailed portraits of the enduring belief systems and dynamic appraisal processes that characterize a given individual's personality structures and processes.

Theoretical Assumptions

Theoretical assumptions, unlike pretheoretical constraints, are scientific beliefs associated with conceptual approaches in the study of personality. Personality psychology has, throughout its history, harbored alternative theories. The theories differ in the assumptions they make about the phenomena that are most important to target in research, and the methods through which those phenomena can best be understood. Ideally, researchers would be cognizant of these assumptions and would select research methods that are consistent with the explicit and implicit assumptions of their favored theory.

Conceptualizing and Assessing Dispositions

One domain where theoretical assumptions shape methodological choices is the study of personality *dispositions*, that is, individuals' affective, cognitive, and behavioral tendencies. All major approaches to personality aim to assess and understand dispositions. However, approaches differ not only in their favored methods for assessing dispositions, but also in their beliefs about the psychological phenomena that constitute individuals' key dispositional tendencies.

At present, there are three major approaches to assessing dispositions: trait-based approaches, which rely on global and nomothetic measures; social-cognitive approaches, which often employ contextualized and idiographically tailored measures; and narrative approaches to the study of the individual, which call for qualitative methods of research.

Dispositions as Context-Free Tendencies

Trait-based approaches endeavor to assess individuals' global, context-free dispositions. They generally do so using measures whose test items refer to trait-relevant behavior, cognitions, and attitudes. Responses to the items are aggregated, that is, are averaged together and used to predict individual actions or general trends in individuals' behavior.

The aggregation process reveals the context-free assumption embedded in the trait approach. Once one averages together responses to test items that reference different circumstances (e.g. items that reference social behavior toward friends and toward strangers, which are found on popular measures of extraversion), information about the potential role of social context is lost. Inferences made from these measures thus implicitly assume that behavior is substantially temporally and cross-situationally consistent; that is, one's trait-relevant behavior in one situation should generalize to other situations.

The most popular example of this approach is the Five Factor Model, which grew out of two important milestones in personality psychology in the twentieth century: the lexical hypothesis and factor analysis. Advocates of the lexical hypothesis used factor analysis to reduce the thousands of adjectives in the English language to anywhere from two to 16 dimensions. More recently, however, five dimensions of personality (Neuroticism, Extraversion, Openness to Experience, Conscientiousness, and Agreeableness) have been recovered using these methods, both across time and across languages. In addition, some theorists assume that trait dimensions derived from factor analytics are both descriptive and explanatory; that is, they both describe differences among people and explain why they occur. Traits in this view are mechanisms that underlie dispositional tendencies in behavior.

Contextually-Linked Dispositions

An alternative conception of dispositions derives from social-cognitive approaches, which posit that personality and behavior can only be understood in context. The enduring beliefs and cognitive appraisals that are central to personality functioning inherently pertain to the potentially idiosyncratic contexts of individuals' lives. Social-cognitive approaches thus abandon the assumption that personality dispositions consist merely of decontextualized average tendencies; instead, distinctive variations across context in thought and action may distinguish individuals from one another.

This theoretical assumption has direct implications for research methods. Rather than measuring trait-relevant behaviors across a variety of situations and aggregating across them, social-cognitivists commonly represent the responses of an individual to each of a variety of circumstances. For example, research on self-efficacy mechanisms may assess individuals' beliefs about their capabilities to cope with each of a variety of specified challenges. *If … then …* profile analyses of social behavior chart variations in behavior across a range of psychologically significant situations. Idiographic analyses of knowledge structures and appraisal processes aim to assess not only the distinctive beliefs of the individual, but also the potentially distinctive sets of situations that activate those beliefs. These idiographic research methods are similar to traditional case studies in that both strive to portray the richness of the psychological life of the individual in his or her life contexts.

Throughout, the theoretical assumption guiding social-cognitive research is that a consideration of situations is of central theoretical relevance to the assessment of personality. Cognitive and affective structures (e.g. belief and knowledge structures) and processes (e.g. situational and affective appraisals) are mechanisms of personality that emerge through reciprocal interactions with the social world. Environments affect personality structures and processes, which in turn partially contribute to which situations individuals experience and how they appraise them. Personality emerges from a dynamic and complex interplay between personality processes and structures, which collectively may be called personality systems, and the social world. These theoretical assumptions guide the selection of research methods.

Narratives as Cognitive-Experiential Dispositions

A third approach with interesting implications for the conceptualization of disposition is the family of narrative approaches, which assert that a core of personality is the narratives, or life stories, that individuals construct throughout their lives, both retrospectively and prospectively. The enduring tendency to express one versus another type of life story constitutes a central personality disposition in this view. Relatedly, some theorists highlight the fact that much of mental life is structured as a linguistically-mediated discourse, with individuals engaging in dialogues – including internal dialogues with imagined others.

Such narrative approaches assert that personality cannot be fully defined by traits or by cognitive and affective processes. Thus, asking someone either how they are in general or how they are in two distinct situations does not assess personality. Instead, personality must be assessed by qualitative research methods that yield a thorough understanding of an individual's life story, and the particular themes they recruit to tell it. Researchers may, for example, seek to identify these that characterize the life-story narrative of an individual, or perhaps a group of individuals who share sociohistorical circumstances.

In sum, theoretical assumptions shape the conception of what constitutes the core dispositions of personality that define the individual and distinguish individuals from one another. These diverse conceptions, in turn, inherently call for different methods of assessing dispositional qualities.

Linking Theory and Data-Collection Methods

In addition to the study of dispositions, a second issue for which theoretical assumptions shape methodological choices is the selection of data-gathering tools. Personality psychologists have long recognized that these tools include self-reports, observer reports,

and laboratory methods (including "implicit" techniques) that reveal personality qualities in an indirect manner. Different theoretical positions highlight advantages, and disadvantages, or alternative methods.

Self-Report Methods

Self-report measures assume access, accuracy, and honesty. If self-report measures are to be both reliable and valid, then people must have conscious access to the information they are asked to report. Sometimes this access is an explicit theoretical claim; for example, humanistic theories of personality highlight people's conscious perceptions of self, social-cognitive approaches claim that people's capacity for self-reflection gives them consciously access to thoughts involving personal capabilities for performance and personal goals for future action, and narrative approaches the human capacity to formulate and express one's life story. Yet, at other times, theorists rely on the veracity of self-reports without making the conceptual basis of that reliance explicit. Consider trait approaches, which historically have relied heavily on self-report measures. Accuracy is critical in trait approaches; if someone believes that she is very agreeable, even when she is not, her personality will be mis-classified in a traditional trait framework. Despite this reliance, trait approaches rarely support the presumption of accuracy by detailing the cognitive processes through which people make judgments about their tendencies and preferences, and explaining how these processes can be trusted to yield accurate judgment.

The researcher can select from among several varieties of self-reports, all of which share the previous assumptions as well as possessing approach-specific assumptions. The most commonly-chosen option is retrospective self-report measures, in which participants use scales to rate themselves or their past behavior over a specific period of time that ranges anywhere from the previous several hours to "in general." Retrospective reports typically assume that individuals would rate themselves or their behavior the same at another time, such as the time the behavior occurred; that is, over replications of the same questionnaire, participants' reports should be reliable.

If one questions the accuracy of retrospection, or if one's theory highlights the need to assess antecedent events and contexts (rather than context-free tendencies), one may opt for self-reports that are based on experience sampling, or ecological momentary assessment. PDAs, beepers, or cell phones signal participants, who respond by reporting on their current or immediately prior experience. Three advantages of experience sampling stand out: the ability to assess the contexts in which experiences occur; the enhanced validity that results if, as memory research suggests, more proximate events are judged more accurately; and the statistical representativeness that results if experience sampling is performed at random times.

A final type of self-report is interviews, which generally are conversations consisting of mostly open-ended questions that may be structured (i.e. a set list of questions from which the researcher is not to deviate), semi-structured, or unstructured. Theoretical assumptions may drive the choice of interview methods. Theories that highlight the narrative and dialogical qualities of mental life inherently suggest that numerical ratings scales are insufficient to capture personality, and must be supplemental by methods that employ natural language.

Observer Reports

Observer-report measures, like self-report measures, make assumptions about people's access to personality-relevant information, their accuracy in forming judgments, and their honesty in reporting those judgments to psychologists. However, observer-report measures assume these qualities not on the part of the person being assessed, but on the part of an observer of that person.

A set of theoretical beliefs motivates the use of observer-report measures. One may believe that individuals lack self-insight or that they are motivated to distort their true self for the purposes of positive self-presentation. In addition, one may claim that individuals are *less* likely to distort personality judgments when reporting about others than when reporting about themselves; for example, self-ratings may reflect a desire to rate oneself as higher than the average person on a variety of trait and performance dimensions (the so-called better-than-average effect), whereas observer's ratings should be less biased in this regard. If one presupposes that observers of social behavior are relatively accurate judges of others' actions and qualities, then observer reports are a sound data-collection tool.

In addition, observer reports rest on a deeper assumption, namely, that behavioral observations made in relative ignorance of the personal history and subjective experiences of the observed individuals are a valuable source of data in personality science. Observers can categorize actions as being indicative of one or another trait category. But, especially when observing people who they do not know well, observers may be unable to identify the meaning of the actions of the individual observer, from the perspective of that actor. Different individuals commonly engage in the same type of overt action for qualitatively different reasons.

Observer reports typically come in two main varieties: retrospective reports and behavioral observations. Retrospective reports might either be standalone assessments of a target's personality or a supplement to a target's self-rating. Retrospective observer reports, like retrospective self-reports, assume that observers would rate a target the same at different points in time and if they were experiencing that person or their behavior in context. In other words, they assume that retrospective reports reflect naturalistic assessments.

As with experience sampling, when one is interested in the contexts within which personality data are obtained, behavioral observation methods are a naturalistic contextualized alternative. Behavioral observations typically involve observers who are trained to assess individuals' behavior and environments in particular ways and record them using a predetermined format. Observations may be done using a rating sheet or simply by taking field notes. Observations may be done in person or filmed and replayed at a later point in time. More recent computer scientists have created software programs that recognize facial expressions and some simple and complex behaviors. Although relatively new, these programs are continuously updating and can flexibly expand to include any well-defined behavior. They drastically reduce the time needed to analyze behavior, but are expensive. Thus, a researcher must weigh the cost of using such a system with the cost of using human observers.

Laboratory Methods

A third form of data collection can be summarized by the term "laboratory methods." By this, we mean the wide range of research methods designed to identify personality-relevant inter-individual differences and intra-individual structures through formal scientific

methods that do not rely on the intuitive personality judgments of research participants. These methods, in other words, generally abandon the assumption that research participants have direct conscious access to cognitive, emotional, and motivational contents the personality psychologist wishes to assess. They often bring to bear, in personality psychology, research tools that originally were developed in other branches of psychological science.

The broad range of laboratory methods can be summarized as consisting of three types. One treats responses that are made consciously as indirect indicators of psychological qualities to which people do not have direct conscious access. In research on motivation, for example, participants may be asked to tell stories in response to ambiguous images. Psychological themes that are evident across multiple stories are a sign of underlying motives possessed by the individual. Social-cognitive research on self-concept provides another example. Participants are asked to indicate, as quickly as possible, whether they think a given psychological quality describes them. Investigators time their speed of response. Quicker responses indicate that an individual possesses a highly developed and accessible knowledge structure, or schema, with respect to the attribute. A second class of laboratory methods is psychophysiological. Measures of skin conductance or heart rate, for example, may reveal arousal that reflects a state of anxiety. Finally, brain imaging methods are increasingly used to identify neural systems, and interconnected networks of systems, that underlie personality structures and processes. A recent development of great note is the application of brain imaging methods to the study of "higher-level" personality process such as self-reflection and personal goal setting.

Theoretical considerations often compel the use of laboratory measures. Theories of personality and motivation may claim that individuals do not have conscious access to the motives that drive their own behavior. Theories of self-concept may stipulate the existence of a holistic self that rests on rapid, parallel cognitive processes on which people cannot accurately self-reflect. Such theoretical claims of course require the researcher to pursue alternatives to self-report measures.

Pragmatic Choices

The above discussions highlight ways in which methodological choices are shaped by theoretical concerns. However, in practice, these choices also are shaped by pragmatic considerations. Basic and applied psychologists often wish to accomplish practical goals, such as the prediction of future behavior from inter-individual differences in personality test scores, and select methods that combine statistical power with efficiency.

Bandwidth

When selecting from among the field's many measurement instruments, a major consideration involves "bandwidth." In psychological testing, bandwidth refers to the range of phenomena to which a test applies. Assessments that each pertain to the same type of psychological process can vary in their range of applicability – that is, in their bandwidth.

Consider, for example, assessments of anxiety. One could assess anxiety with respect to a specific social context (e.g. public-speaking anxiety), or social contexts in general (generalized social anxiety), or – if one wanted an anxiety measure of maximal breadth – with no specification of context (i.e. global trait anxiety).

In applications, the choice of bandwidth can be made on pragmatic grounds. As a general rule, prediction accuracy is maximized when the bandwidth of a personality measure matches the breadth of the outcome one wishes to predict. If one is screening applicants to a job with diverse duties, each of which requires conscientious behavior, one may base selections on a measure of general conscientiousness. But if one were trying to predict performance in a narrow set of circumstances, such as maintaining attention to tasks even when under stress or experiencing setbacks, a measure of less breath would be preferred.

The principle of bandwidth applies not only to measures of behavioral dispositions, but also to measures of cognitive personality variables. One example is self-efficacy beliefs. One could assess self-efficacy beliefs with respect to a specific activity (e.g. in an academic setting, students' subjective beliefs about their capabilities for performance on an upcoming exam), or with respect to a broader class of activities (e.g. attaining high grades in one's major in college), or one could assess generalized self-efficacy beliefs, that is, an overall sense of one's level of behavioral competencies. Again, a match between the breadth of the measured construct and the breadth of the outcome of interest will benefit prediction. For the pragmatic purpose of predicting future behavior, one might only select the generalized measure if one were predicting an aggregate of performance across a diverse range of activities. A disadvantage of the broad-bandwidth measures is that they sacrifice information about within-person variability from one behavioral challenge to another.

Medium of Data Acquisition

Personality psychologists also face pragmatic choices when selecting the medium to use to collect data, that is, the means through which one communicates with individuals to acquire data. At present, three broad categories of media predominate: in-person, remote, and Big Data analytics. Although the choice from among media should be made carefully, this choice generally cannot be based on formal principles of personality theory. It instead rests on pragmatic factors, including available resources.

In-person media include self-report inventories, observer reports, and interviews, each of which has been described previously. Advantages of in-person measurements include participant engagement and experimental control. Personal interactions with an experimenter can make participants more accountable for their responses; that is, participants are likely to be more careful in making responses. The experimenter, in turn, can enhance experimental control by ensuring that all participants complete the task under similar conditions. Both advantages can reduce the chance of Type II error in research on individual differences. These advantages, however, come at a price. The logistics of in-person data collection (acquiring lab space, recruiting participants and bringing them to the place of data collection, preparing experimental materials, executing random assignment, and so forth) are costly. Experimenter-demand effects, such as participants' desire to make a good

impression on the experimenter, are possible and must be reduced. Because in-person studies can be costly and laborious, one may choose to collect data remotely.

In remote data collection, investigators may communicate with participants through electronic means such as the internet or smartphone apps. Key advantages of such remote data acquisition include the speed of data collection, a reduction in experimenter effects, and greater ease in recruiting diverse samples that are representative of the population at large (since one can reach individuals anywhere in the world who have internet access). In addition, participants may answer some types of research materials more honestly when afforded the anonymity of remote responding. Historically, these advantages were achieved by mailing out surveys and waiting for responses to be returned. Today, however, it is more common to employ web-based platforms (e.g. Qualtrics) that make participant responses immediately available to researchers. Faster and sometimes cheaper data collection through remote means comes at costs that may include decreased participant engagement, biases that result when individuals choose not to respond to materials, and reduced experimental control. Unlike in-person studies, participants in remote studies complete tasks when, how, and at what pace they choose. Thus, experimenters cannot be sure participants are attending fully to the task and not, for example, multitasking. Although more common with mail-in studies than with online studies, recruited participants may also choose not to respond. This non-response bias may limit the representativeness of the sample and impact results of a study. Decreased engagement, multitasking, and non-response bias are all examples of decreased experimental control in remote studies. That is, experimenters cannot be sure that certain variables are held constant, which may limit the inferences that can be made from collected data.

The third medium, Big Data analytics, has been triggered by the availability of very large-scale digital storage. Social media and internet shopping sites may store hundreds of choices and expressions by millions of users. The stored data sets are so large and complex that traditional statistical tools may be inadequate for their analysis. Researchers thus may seek to identify structures in the data sets through data-mining techniques that combine traditional statistics methods with alternative methods such as neural network methods or "decision tree" analyses that represent underlying structures in the data. A substantial advantage to Big Data methods is that one is analyzing actually-occurring behavior (on the internet), rather than asking individuals to reflect upon their typical behavior. However, too strong a focus on Big Data collection and analysis also has drawbacks. Because these data also are in some sense remote, the exact conditions in which responses occur may be unknown, and many data sets lack experimental control. In addition, it is difficult, in Big Data analytics, to employ measures that might indicate the beliefs, goals, and affective mechanisms underlying a given individual's responses (including the laboratory measures discussed above).

Both of the latter media, remote data-collection methods and Big Data analytics, promise to overcome psychology's traditional over-reliance on participant samples that are Western, educated, industrialized, rich, and democratic – or, as the popular acronym summarizes, WEIRD. This is a substantial advantage. Yet one must recall that many of the advances in the history of personality have derived from studying individual persons in depth, across time, and in context, and from the use of measures of cognitive and affective mechanisms that require laboratory-based procedures. A challenge for the field is to capitalize on recently-developed remote technologies without losing the richness and psychological sophistication of psychology's panoply of research methods that require in-person interaction with the individual.

Cross-Cultural Research, Methodological Issues of

Tyler L. Collette and Richard L. Miller

Texas A&M University–Kingsville

Human societies engage in a wide variety of behaviors, practices, expressions, organizations and conflicts. They vary in the construction of social roles, norms and beliefs. These variations exhibit both coherence and cleavage. Similarities between and among cultures can come about as a result of geographical proximity, historical relationships, for example trade, and common languages and origin. Cross-cultural research engages in systematic comparisons of two or more cultures or two or more cultural syndromes in order to determine the occurrence, distribution, and causes of cultural variation and complexity across domains. Many cross-cultural studies address the question as to whether the knowledge of psychology, we believe to be true, is applicable to all human beings or only to some people in some cultures. One important goal of cross-cultural research is to arrive at general principles and general explanations that apply across cultures.

Cross-cultural research can contribute to psychological theory by identifying groups whose behavior does not conform to established theories and by expanding on the number and types of independent variables that we use to test our theories. In psychology, there are three variations in how cross-cultural research is conducted. First, cross-cultural studies can either be exploratory or can test specific hypotheses. Exploratory studies adopt an open-minded perspective on the nature and size of possible cultural differences, while studies that test a particular hypothesis rest on an assumption about the nature and size of the cultural difference derived from existing theory. Second, cross-cultural studies can examine the differences in human behavior between residents of different countries or members of different ethnic groups. These studies are sometimes called structure-oriented. An example would be a study of the measurable intelligence of two different culture groups. Alternatively, research may focus on specific characteristics of a country or ethnicity that relate to certain psychological variables. These studies are sometimes referred to as level-oriented studies. For example, a study of the relationship between certain "intelligences" related to cultural practices would be a level-oriented study. Finally, cross-cultural research can compare how different cultures influence the understanding

of specific constructs, for example what is meant by moderate punishment. Research could also examine the causes of different outcomes, for example the interpretation of score levels on psychological tests.

Historical Overview

While there are examples of cross-cultural comparisons that date back to early Greek writers such as Hecataeus of Miletus and Herodotus, most texts date the formal introduction of cross-cultural research to the late nineteenth century, beginning with Edward B. Tylor's statistical methods for conducting cross-cultural analyses. Some early cross-cultural researchers include W. H. R. Rivers (1905) who conducted studies of visual perception across cultures and E. G. Sumner, who wrote a four-volume work on the "Science of Society" and coined the term ethnocentrism. Another early cultural psychologist was Wilhelm Wundt (1916) who authored a multivolume work devoted to understanding folk psychology.

Etic vs. Emic

Etic and emic refer to two different approaches to field research that either gather data from the perspective of the individual within a particular social group (emic), or from the observations and interpretations of the outside researcher (etic). This distinction was originally created by Kenneth Pike (1954) to describe phonetic similarities and differences in language, but has since been transformed to describe various culturally specific or universal aspects of human behavior.

Within cross-cultural psychology the term etic is used to describe universal psychological truths that are fixed across all cultures. Emic refers to the cultural differences of psychological aspects that are specific to particular cultures. This approach has led to extensive testing of the tools researchers use when gathering data within and between cultures. Harry Triandis was an early proponent of testing the validity and reliability of psychological measures for clear and identifiable differences (Triandis & Marin, 1983). His work found that scales designed for a specific culture were more likely to find cultural differences than those that were created with the assistance of members of all of the cultures being studied. Research in this area has highlighted the importance of creating equivalent measures in order to determine which psychological principles can be considered universal, and which should be considered culturally specific.

Types of Questions

Cross-cultural research aims at understanding cultural differences, their causes, occurrence and consequences. The first question a cross-cultural researcher may ask is a descriptive one on the prevalence within a cultural group including human communities of a specific practice, belief, social role, norm, expressions and forms of organization and conflict. The second question is what are the sources of coherence or non-coherence in these behaviors.

This question could explore common history, language, and identity. It could also examine common or recurrent modes of adaptation to the environment or other sources of common human problems. The third type of question asked is what are the consequences or effects of a particular trait or expression. For example, are certain cultural differences the source of conflict or co-operation between cultures? Finally, cross-cultural researchers often ask relational questions such as how one aspect of culture, for example type of marriage is related to another aspect of culture, for example patriarchy.

Research Methods

There are a wide variety of research methods available for cross-cultural studies including correlational approaches, true experiments, observation, surveys/interviews, and projective tests.

Correlation refers to how two measurable variables are related to one another. An example of a cross-cultural correlation would be Aknin et al.'s (2013) work that explored how prosocial spending is related to well-being across 136 countries. A true experiment manipulates an independent variable in order to observe its effect on a measurable behavioral process. A priming study by Trafimow, Triandis, and Goto (1991) manipulated American and Chinese students by priming them to think in either their individual or collective identity. This prime had a significant effect on how they responded to a self-attitude measurement. Those primed individually responded from an individual perspective, and vice versa. Surveys and interviews can be used in a similar fashion once equivalence is established. Surveys can be used to determine how attitude and behavioral measures relate to particular attitudes. A good example of this is Buss' (1989) study of human mate preferences. Interviews can serve a similar purpose while allowing the researcher to gain a more detailed understanding of a participant's response to a particular question. Lastly, projective tests, like the Thematic Apperception Test, allow cultural research to be done without the barrier of language. Hudson (1960) used a variation of the TAT among the Bantu and found interesting variations in perception. The Bantu did not see relative size as an indication of depth within the picture. Hudson's findings showed that experience with European culture was an important factor in depth perception.

Establishing Equivalence

It did not take long for cross-cultural research to realize that the concept of equivalence was an important issue in reporting valid and reliable results. It was clear that simply translating a measure into another language would not produce accurate results. Equivalency, within a cross-cultural context, can refer to language, conceptualizations, and empirical methods, each of which needs to be equivalent for the cultures being studied. Assurance that the language in your measures are equivalent can be achieved through the process of back-translation. This process requires cultural researchers to have their measures translated into another language, and then have it translated back into the initial language, by a different translator. If the measure is translated accurately back into the initial language, it can be said it is

linguistically equivalent. Conceptual equivalence refers to the actual meaning that a measure is attempting to gauge, and can be difficult to define accurately. For example, the term moderate as applied to punishment might mean "time out" in one culture and light paddling in another. Conceptual equivalence is generally achieved through in-depth interviews with participants of a particular culture, and through an extensive review of prior research done on a particular culture. It is vital that researchers establish the conceptual equivalence of their measures before conducting research to insure the validity of their results. In addition to conceptual equivalency, researchers must be certain they establish equivalent empirical methods. This includes equivalency in sampling, measurements, and procedures. Sampling equivalence refers to the extent to which the samples are representative of their culture and equivalent on demographic measures such as age, sex, majority/minority group membership, etc. To achieve measurement equivalence, the researchers must insure that the measures used are valid and reliable and that the wording in the measures passes the test of linguistic equivalence. Procedural equivalence becomes important when choosing participants. For example, is a student at a public school in one country similar to a student in a public school in a comparison country? Equivalency is key when conducting cross-cultural research, and is an important consideration that assures that researchers are taking every possible precaution against bias.

Bias

While non-equivalence can be a source of bias, there are also methodological biases that can distort data, such as sampling and procedural biases. Sampling bias can occur in two ways: the sample may not be representative of the population considered, and the two samples may not be equivalent on non-cultural aspects. For example, university students in South Texas (Americans) cannot be equivalently compared to Australian stay-at-home moms (Australians). We cannot accurately state that the two groups are representative of the greater population, and the two populations themselves are not demographically equal. Procedural bias refers to cultural differences in the collection of data that can affect the results. For example, in many psychology programs, it may be required for students to take part in research being done at the institution. However, another culture may see this type of requirement as deeply insulting, coercive or exploitative. How these two different groups understand their role in the research can differ dramatically depending on the context of their participation. Therefore, it is important that researchers understand these types of biases in their own study, and create effective procedures that are equivalent across the cultures being researched. Other important types of bias to consider are response bias and interpretation bias. Response bias refers to a methodical inclination to answer a particular way on research measurements. For example, socially desirable responding, giving answers that make oneself look good in one culture can lead to a misguided comparison between cultures. One culture may have a stronger emphasis on socially desirable responding on a particular subject than does another. As a researcher you must consider the cultural influences that may cause response bias within a particular culture. In many cases, response bias can lead to interpretation bias or the biases in the analysis or methods used to interpret the data. For example, a Likert scale may allow for

analysis of variance to be conducted. Statistical significance may show that one population responded higher on one aspect than another culture. This however leaves out an important aspect of cultural research. Conception of what the threshold items on the Likert scale mean can be vastly different between cultures. Therefore, in one culture the response *highly agree* may be another's *slightly agree*. As a researcher, steps must be taken to insure that the participants' understanding of the measurements is similar in order to accurately interpret the data.

Ethics

While cross-cultural researchers must observe all of the ethical principles outlined in the Helsinki Declaration and the Belmont Report, including fair recruitment of participants, informed consent, avoiding harm, confidentiality, working with vulnerable populations, and debriefing, there are also ethical concerns unique to cross-cultural research. The first ethical principle applies to design of the research study. Research findings on cultural differences can be used to reinforce powerful negative stereotypes regarding a cultural group and can even lead to oppression of a cultural group. Researchers must be careful to not over-interpret or over-apply their findings and to guard against applying untested assumptions about the roots of cultural differences. A second ethical concern relates to how researchers define culture. While a textbook definition may point to invariation in meaning shared by a group, transmitted across generations, that meets the survival needs of the group and provides purpose to life, researchers often boil it down to differences between nationalities, racial, or ethnic groups which can perpetuate stereotypes. One way to address this concern is to examine not group differences but instead differences in cultural syndromes such as individualism/collectivism, power-distance or masculinity. Another ethical concern involves what constitutes a sensitive topic or a vulnerable population. It should not be assumed that what is not sensitive in one culture is equally not sensitive in another culture. For example, in Western society, sex and sexuality are open for discussion whereas in many parts of the world, for example, homosexuality is a serious crime and both research participants and researchers can suffer from asking questions about a forbidden behavior. Other ethical concerns include ownership of the data, interpretation of the data and dissemination of the data. Many of the ethical issues involved in conducting cross-cultural research can be overcome by including colleagues on the research team who are from the culture or cultures being studied.

Idiographic vs. Nomothetic Research

Elvis W. DeFreese and Gerald E. Nissley

East Texas Baptist University

Many researchers tend to use primarily nomothetic or idiographic assessments and data. It seems to be only occasionally that a researcher will use both nomothetic and idiographic assessments and data in order to help interpret the results of their studies. The nomothetic approach to assessment and data is all about generalizable data. The nomothetic approach has different paradigms at its disposal that allows it to operate both from large samples and group-based statistics as well as small samples and case-by-case study analysis. Nomothetic knowledge aims to find generalities that are common to a particular class and derive theories or laws to account for those generalities. In other words, nomothetic approaches seek to project data from large samples onto individual cases. For example, nomothetic data would show, on the National Crime Report (NCR) compiled by the Federal Bureau of Investigation (FBI), the statistical demographics of those perpetrators of the majority of certain types of crimes. So, if the majority of all "white collar" crimes are committed by white men between the ages of 40 and 55 years old, and if a "white collar" crime is committed and the police use nomothetic data, then they will likely focus on those suspects that fit the profile from the data, which in this example would be white men between the ages of 40 and 55. The idiographic approach, on the other hand, is more concerned with specific details. Idiographic judgment involves the particular details of an individual's experiences, life history, and values. The idiographic understanding is basically the science of an event or of a process. In other words, idiographic understanding is concerned with what used to be or currently is the case for a specific situation or individual. Idiographic knowledge aims to describe and explain particular phenomena. Idiographic especially looks at in-depth individual personality traits. Idiographic measures are not based on a specific method of research. Idiographic is more of an objective to accomplish than a specific research method. So, using the same example from above, if a "white collar" crime is committed and the police use idiographic data, then they would be using case-specific clues and evidence to lead them toward a viable suspect list. While nomothetic and idiographic assessments have their differences, they were never meant to be used separately. They were to be used together in order for the researchers to gain a clearer understanding of the situation.

There are several idiographic measures that are based in different approaches. The first type of idiographic measure to be discussed is game-based idiographic assessments. These assessments built into games and simulations are the cutting-edge in the next generation of assessments. Some researchers suggest that the principles of evidence-centered assessment design can improve game-based assessments. Participant information can be gathered, analyzed, and systematically used to validate claims and inferences about performance in ways that are fun, engaging, and potentially able to assess the individuals without their knowledge. Furthermore, some researchers describe how game tasks can be modified to include certain psychometric properties, such as task difficulty and task discrimination in order to support the construct validity of game-based assessments. Participant creativity and persistence are not normally assessed for in traditional assessments, but in a game-based assessment both of these characteristics can be measured in addition to other cognitive and affective characteristics. Some researchers have found a potential for a relationship between game-based assessments and an idiographic approach. The second approach comes from the dynamic assessment (DA) intervention. The two main ways of measuring DA interventions involve split-half tests and integrated scoring systems. However, there is a gap between research and practice of DA interventions. Some researchers have worked on developing a methodology that is compatible with the research and practices, especially split-half tests and integrated scoring systems. These same researchers developed an idiographic method of measurement that involves multidimensional scaling (MDS) and general procrustean analysis (GPA). This method of measurement was found to be compatible with both individual intervention and suited to building a body of evidence-based research for DA. The third approach or area to idiographic assessments involves measuring self-esteem. Idiographic implicit association tests have been found to have a stronger correlation with self-esteem than generic implicit tests. Idiographic assessments also found a higher incremental validity for unprovoked aggression when interacting with explicit measures of aggressiveness. In other words, more specific idiographic stimuli are more effective in self-concept and self-esteem.

Idiographic assessments have also been used for testing the anxious reactivity of traumatic event script-driven imagery when searching for a relationship between sleep quality and post-traumatic stress disorder (PTSD). Another idiographic measure that has been developed is called the sentence completion test for depression (SCD). This idiographic measure uses incomplete sentences, which the participant has to finish, in order to produce specific information that measures the individual's level of depressive thinking. The SCD has been found to have good construct validity, internal consistency, inter-rater reliability, sensitivity, and specificity. This assessment helps evaluators to generate hypotheses by working complementarily with questionnaires, and do so without losing any validity or reliability on the nomothetic level.

The nomothetic approach includes quantitative methods such as structured techniques and psychometric instruments. These psychometric instruments are made up of a series of questions and statements which are referred to as items. When these psychometric instruments are used in personality inventories, the participants are asked to report if and how much the items describe their behavior by using a category rating, most often a Likert scale. This allows evaluators the possibility of comparing both individual and/or group performances with normative data. The nomothetic approach typically involves lots of

people gathered in one place participating in very structured and standardized tests. How clinicians interpret the data from academic achievement and intelligence testing often involves nomothetic data. The score of each item on the assessments is correlated to how a specific age group or other demographic group answered those items. For example, if someone scores a 100 on an intelligence test, because researchers have access to nomothetic data they can interpret that the participant with this score is within the normal intelligence range for their age and other demographic.

There are biases for both nomothetic and idiographic assessments. Most of these biases come when researchers use one or the other type of assessments. Those who use nomothetic data only will often end up overlooking those specific details of an individual that would alter the interpretation otherwise. Those who use idiographic data only will often not understand how their client fits into the bigger picture or which interventions to use with their issue due to the lack of data from other studies. Assessment centers and development centers are used by organizations to evaluate and train people. These centers use methods and techniques, such as interviews, that are derived from an idiographic approach. They also use methods and techniques, such as standardized tests, that are based on a nomothetic approach. This process is used because it is believed that collecting data from these varying perspectives will allow for a more integrated judgment of people during the evaluation. An increased amount of data, while difficult to manage, helps assessors to feel more confident in their judgments, but research has shown that an increased amount of data does not help increase their accuracy. What does help is their level of competency in interpreting results and in the competency of their staff who administer the assessment measures. The use of these two approaches seems to be appropriate based on how different the personality characteristics of people are. The point is that it can be challenging to sift between what is relevant information and what is irrelevant. Deciphering this comes from determining the point of the assessment, and choosing the most valid instruments for measuring the target variable.

In the past several years, there has been a growing concern with the use of nomothetic data within the realm of forensic assessments, forensic pathology, and other law enforcement areas of interest. Nomothetic data is pulled from large groups of people and tends to hold more credibility in risk assessments. However, a current concern is that evaluators may begin depending too heavily on nomothetic data and forget the importance of idiographic data and the influence that it can have on determining a person's level of risk. Idiographic data is important due to the nature of the data being case-by-case specific. This can be useful in determining a person's current level of functioning and capacity, and then comparing that data to previous or future data on their functioning and capacity. The process of conducting a risk assessment is susceptible to a variety of errors that can negatively affect the risk determination, and most of these errors have to do with the nomothetic and idiographic aspects of the risk assessment while the other errors pertain to the integration of both types of data. This concern also includes violence risk assessments. This stems from the question whether or not it is logically, ethically, morally, or mathematically correct to use data collected from groups of people to determine the risk level of an individual. A study was performed that manipulated the extent to which an estimated level of risk is unpacked (listing no, three, or six risk factors). The study found that the degree of "unpacking" increased the likelihood that jury-eligible citizens would commit or convict a high-risk respondent and decreased the likelihood of their committing a low-risk

respondent. The researchers used Support Theory as a basis for their study which means that they took the view that "decomposing a target event increases the perceived likelihood of its occurrence and its perceived risk." In other words, the more specifically a target event is described the more likely people are to perceive an increase in its occurrence. Therefore, when the risk factors involved in a violence assessment are specifically described or listed then it is more likely for violent behavior to occur in those people who responded high on the assessment.

Some of the aforementioned concerns about forgetting either nomothetic or idiographic data in research studies have been addressed in various studies as well. In fact, there has been work performed in creating a nomothetic version of the Brunswikian Lens Model while still allowing the idiographic assessment to work its part of the measure. The idiographic side of the model measures the judgment processes of the individual involved while the nomothetic side of this model examines the evidence for possible generalizability across several individuals. Other studies that have compared time-series analyses and hierarchical linear modeling did so in order to gain a better understanding of how to incorporate idiographic and nomothetic approaches within a study.

Longitudinal Research

Annika A. Martin[1], Andrea E. Grünenfelder-Steiger[2], and Mathias Allemand[1]

[1] *University of Zurich*
[2] *Institut Neumünster*

Longitudinal research refers to a broad category of research designs that involve at least one repeated observation of the same entity over time. Longitudinal designs allow researchers to assess change and stability within individuals in one or more variables as a function of time. In longitudinal personality research, the measured entity over time most likely represents individual differences, such as openness to experience or neuroticism. Traditionally, longitudinal designs have been limited to the collection of data at two measurement occasions with a focus on change either at the group or at the individual level. The collection of longitudinal data at more than two measurement occasions offers valuable information on how individuals change over time, such as the evaluation of the appropriate shape of change, the detection of interindividual or systematic variability in change, the assessment of background variables as meaningful predictors of change, and increased precision and reliability associated with the measurement of change.

There are three important issues to consider in longitudinal research (Collins, 2006). First, a theoretical model of change is necessary to describe the nature of the change phenomenon that is to be observed, such as whether and in what ways the variables are expected to change and what the possible determinants of change might be. Second, a temporal design is required to observe the change phenomenon of interest. The temporal design affords a clear and detailed view of the targeted process, including timing, frequency, and spacing of repeated observations. Third, the statistical model is the direct operationalization of the theoretical model. Though all three issues are important, the theoretical model of change provides the foundation for choosing the appropriate temporal design and thus the most appropriate statistical model.

Examining Longitudinal Change

The main benefit of longitudinal research is that it allows examination of how variables or constructs unfold over time and how changes vary within and across individuals. That being said, it is important to highlight the different perspectives of change and stability, as each of these offers a unique perspective to the change processes under investigation (Allemand, Aschwanden, Martin, & Grünenfelder-Steiger, 2017). First, when studying constructs over time, it is implicitly assumed that the measurement process of constructs is equivalent across measurement occasions. But changes can only be unambiguously interpreted as a reflection of a developmental or change process when items of a questionnaire or experimental stimuli do not change connotation or contribution to the underlying construct over time. Therefore, establishing longitudinal measurement equivalence is an essential prerequisite for the study of constructs over time. Second, structural stability refers to whether a set of indicators demonstrates similar factor structures over time. A stable structure would imply that the positioning of indicators relative to each other remains stable, suggesting that their meaning remains unaffected over time. This type of stability can address the question of whether the correlational pattern among a set of variables is stable over time. Third, rank-order stability refers to whether individuals maintain their relative ranking on a variable of interest in a given sample. In other words, questions of rank-order stability (differential stability) address whether initially high scorers on a variable tend to remain high scorers in a subsequent assessment of the same variable relative to other people. Tests of this form of stability tend to focus on whether initial scores or frequencies correlate with later assessments of the same construct. Fourth, mean-level change refers to the average level change of a construct over a set period of time. For instance, one can ask whether a certain personality characteristic increases or decreases over time, such as when a person becomes more assertive or less neurotic. Mean-level change is found when most people of a sample change in the same way during a specified period of time. Fifth, stability of variance (stability of divergence) reflects whether a sample of individuals demonstrates similar or greater variability on a behavior or construct over time. This form of stability thus examines whether individuals differ with regard to a certain behavior to a similar or variable extent across time. Testing stability of variance often requires structural equation modeling and assesses whether the latent variables of interest show greater variability at one time point than another. Finally, questions regarding interindividual differences in within-person change are among the more interesting ones when studying longitudinal development and change. In this case, change of a variable or a construct overall is not in question, but rather whether individuals show similar levels of change on that construct over time. In analytic terms, this effect often refers to whether significant variability is evident in the slope or change parameters of a given construct. Taken together, the main advantage of longitudinal research designs is that they allow the study of several conceptually distinct ways of development and changing of one or more variables over time.

Longitudinal Research to Study Developmental Change

Longitudinal research differs as a function of the temporal design. One can distinguish between two broad types of research: traditional long-term longitudinal studies and intensive short-term longitudinal studies. Traditional longitudinal research designs are used for

tracking individuals over relatively long time intervals such as several years or even decades (Hertzog & Nesselroade, 2003). The theoretical models of change underlying long-term longitudinal research refer to the development of rather enduring aspects of personality, that is, personality traits that are typically defined as relatively stable patterns of thoughts, feelings, and behaviors over time. Hence, in a theoretical model for long-term personality trait change we would not expect change at a rapid rate but we would rather expect slow developmental processes over longer time periods. Therefore, in a theoretical model of change, it is important to consider the timing, frequency, and spacing of repeated observations that are needed to accurately capture systematic and interindividual differences of change in personality traits. This in turn influences the selection of the temporal design and statistical model. Time intervals that are too short or too long in relation to the nature of the phenomenon being studied can produce data that, in some cases, is overly sensitive to measurement errors and carryover effects and, in other cases, is insensitive to change and variability. Traditional longitudinal studies are typically characterized by widely spaced single measurements, often spanning several years. Those designs are referred to as panel designs or multi-wave designs, since their nature is characterized by repeated waves of single measurements. They typically address developmental change. For example, longitudinal research on personality development has shown that despite their enduring nature, personality traits can change over years and decades and continue to change in adulthood into old age (Allemand et al., 2017). Moreover, research has also shown that developmental changes over and above the levels in personality traits may predict important life outcomes such as health (Steiger, Allemand, Robins, & Fend, 2014).

Intensive Longitudinal Research to Study Dynamic Processes

Intensive longitudinal research designs are used for tracking individuals over relatively short time intervals such as minutes, hours, or days (Bolger & Laurenceau, 2013). The theoretical models of change underlying intensive, short-term longitudinal research refer to dynamic processes of personality such as regulative and self-evaluative processes or emotional states in a given situation that show temporary changes and fluctuations in thoughts, feelings, and behaviors in response to internal aspects such as motives and goals and external situations such as stress exposure. In a theoretical model for short-term personality dynamics, we would expect fluctuations at a rapid rate – assessed with multiple repeated observations over a short time period. Hence, to accurately capture the unfolding of dynamic personality processes, it is important to select temporal designs that are capable of assessing changes and fluctuations from moment to moment in the short term. Intensive longitudinal studies can involve end-of-day assessments over a few weeks, or frequent assessments throughout a day, an hour, or even minutes. The frequency of measurement occasions within the study design determines how fine grained the analysis of temporal associations can be. Therefore, these designs may be less suited to tap meaningful change that develops in a person across a longer period of time but well suited to assess intra-individual variability in terms of fluctuations as a deviation from the person's general mean level or prior levels. Importantly, not all short-term fluctuations contain practically or theoretically important information, but can be caused by measurement error. The study of dynamic processes requires statistical models and

methods that can deal with multiple intensive repeated observations over short time intervals such as multilevel modeling (Bolger & Laurenceau, 2013).

Intensive Longitudinal Research Methods to Study Daily Life

There are several intensive longitudinal research methods used to study everyday thoughts, feelings, physiology, activities, and behaviors under actual living conditions in daily life. For the purpose of this entry, we provide two exemplary research methods. The first example is the diary method (Bolger, Davis, & Rafaeli, 2003). In diary studies, individuals provide frequent reports on variables or constructs of interest on a regular basis, often combined with events and experiences that participants encounter in their daily lives. Data can be collected with the help of traditional paper-and-pencil methods or electronically via the internet or with mobile technologies. Diary methods allow studying dynamic processes outside the laboratory in real life settings and contexts. They tend to reduce the response bias due to retrospection, as diary methods strive for minimizing the time elapsed between experience and measurement of a variable of interest, causing an increase in ecological validity. Additionally, the explicit consideration of the relatedness of change processes to events and dynamics of daily life provides additional or even complementary information to that obtainable by more traditional longitudinal research designs. For example, daily diary studies may reveal that certain personality characteristics are relatively enduring, while others are more strongly related to situational determinants and events, and thus are more variable and fluctuating.

The second example is ambulatory assessment that refers to a broad category of increasingly digitalized methods of experience sampling, including classical self- and other-reports, physiological, and biological data, and observed behaviors (Trull & Ebner-Priemer, 2014). Ambulatory assessment is not necessarily longitudinal, but most research questions using ambulatory assessment involve the study of a certain phenomenon in daily life and across time. Owing to technological innovations such as portable devices, data can be collected actively and passively in real time or close to real time. Increasingly large amounts of psychological relevant data can be drawn using passive assessments of dynamic processes such as physiological parameters. Automating data collection allows studying very complex research questions, covering multiple domains of psychological functioning, but may also involve challenges for future research. For example, continuous measures of processes such as heart rate variability or GPS should be combined with self-report measures that are only assessed at a certain point in time or when a certain event occurs. Moreover, ambulatory assessment methods produce an intense amount of data, in fact leading to data analytical issues, challenging and stimulating the development of psychological theory as well quantitative methods of longitudinal research.

Integrating Developmental Change and Dynamic Processes

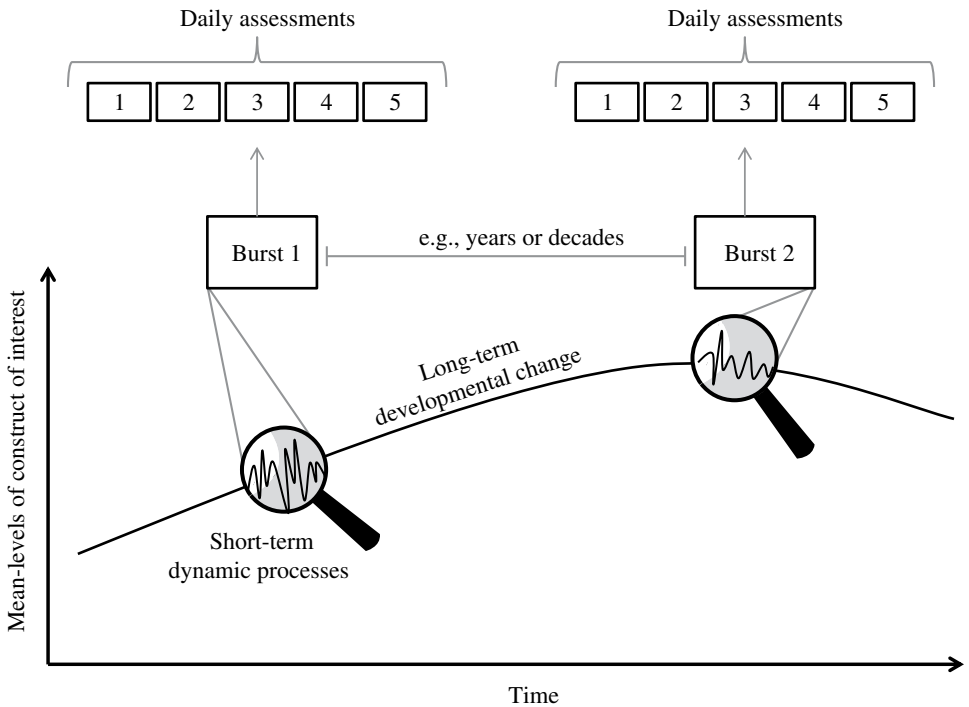
The measurement-burst design involves longitudinal assessments that are planned around closely spaced successive "bursts" of assessments, rather than widely spaced successions of single measurement occasions (Nesselroade, 1991). It combines features of intensive


Figure 1 An illustration of a measurement-burst design.

short-term longitudinal methods such as diary methods with features of long-term longitudinal designs that are used for tracking individuals over relatively long time intervals (see Figure 1 for an illustration). This type of design provides researchers with the unique opportunity of modeling long-term developmental changes of personality traits over years in tandem with dynamic processes of personality expressions that can only be measured on a daily or momentary basis, such as regulative and self-evaluative processes or emotional states in a given situation (Sliwinski, 2008). Therefore, the measurement-burst design can be seen as a hybrid of the two broad types of longitudinal research designs in order to improve the detection of long-term change and short-term fluctuation and allow for simultaneous examination of both components into a single study. Within the logic of measurement-burst designs, both short-term fluctuations as well as long-term developmental changes are viewed as systematic sources of individual differences in development. Both sources of variability may be of important predictive value for outcomes of interest. For example, certain personality characteristics may carry different informative aspects with respect to a long-term perspective (e.g. people may differ in how their personality traits develop as they move from adolescence to early adulthood and beyond) and a short-term perspective (e.g. people may differ in how strong their personality state expressions fluctuate on a daily level). In that sense, implementing measurement-burst designs seems to carry special value when the constructs of interest might be affected by longitudinal processes at different time scales.

Person-Situation Interactions

John F. Rauthmann

Universität zu Lübeck

Person-Situation Interactions

Personality is defined via general tendencies of affect, behavior, cognition, and desire, also referred to as *traits*. Thus, traits are fairly abstract and removed from specific mental processes or behavior occurring in specific situations, also referred to as *states*. Nonetheless, traits are expected to predict momentary states, and states should show some evidence of consistency across different situations or time if an underlying stability-generating personality system is to be inferred. States, as manifestations of personality traits, always take place in specific situations (Fleeson & Jayawickreme, 2015), so we need to understand how personality and situations are linked. For example, Funder (2006) refers to a "personality triad" consisting of persons, behavior (including mental processes), and situations which are interwoven in complex ways. Any member of this triad could then be understood in terms of the other members. This is inspired by Lewin's formula $B = f(P, E)$ where momentary behavior B is a function of the momentary mental state of the person P and his/her actual environment E. Lewin understood the person and environment to be part of a common "field" so that they would need to be studied jointly. Later, Funder (2006) reconceptualized this Lewinian notion to $B = f(P, S)$ where behavior is a joint function of the person P and the situation S. He also concluded that $P = f(S, B)$ and $S = f(P, B)$ must hold if true interactions among P, B, and S are captured. However, understanding how persons – with their personality traits – and situations contribute to behavior and, more generally, how the variables of this personality triad are interrelated has been a contentious issue of personality and social psychology, sparking the *person-situation debate*. This debate broadly revolved around the question whether personality or situations represent the dominant predictors of behavior. One answer was that personality and situations *interacted* with each other – that is, to explain and understand behavior, we should not study persons and situations separately but attend to their conjoint effects (i.e. interactions). Later, psychologists sought to understand which *mechanisms and processes* constitute such person-situation interaction effects.

The Person-Situation Debate

What came to be known as the person-situation debate revolved around several issues that were supposedly shortcomings of personality and traits as concepts of scientific inquiry (see Fleeson & Noftle, 2009 for an overview). First, the moment-to-moment consistency of behavior has been deemed too low to warrant the concept of a stable trait (e.g. Hartshorne & May, 1928). Thus, the reasoning went that situations determine behavior. Second, traits did not seem to predict behavior too well (e.g. Mischel, 1968). Thus, the concept of "personality" was declared empty and useless. To defend the concepts of personality and traits, several strands of research showed that people are in many ways remarkably consistent and that traits exist, are meaningful, and can be deemed consequential for people's lives (Kenrick & Funder, 1988).

Among the responses to the person-situation debate were lines of research that strived to combine the person and the situation – that is, person-situation interactions – because neither on their own would be sufficient to explain, predict, and understand behavior. The first line, referred to as *interactional psychology*, was devoted to a statistical understanding of a person × situation interaction effect beyond main effects of persons and situations. The second line, here referred to as *person-situation transaction research*, emphasizes what it conceptually means if a person and a situation "interact." These two lines explicitly address the person-situation debate by acknowledging that both person and situation variables are important, but that they may be entangled in complex ways.

Interactional Psychology

Most of psychology treated the Lewinian formula as if behavior were an additive function of person and environment variables. This would mean that behavior is *independently* predicted by traits and situations to some extent. It is this notion of person-situation independence that creates the possibility to pit the magnitude of person and situation effects against each other. In contrast, Magnusson and Endler introduced an *interactional psychology* (Endler & Magnusson, 1976) with the main tenet that behavior is a multiplicative function of the interaction between traits and situations. Statistically, a significant and substantial interaction effect (beyond the main effects of traits and situations) would mean that effects of traits depend on situations or, vice versa, that effects of situations depend on traits: traits moderate situation effects, and situations moderate trait effects. Conceptually, this means that certain people respond to certain situations differently from others (or that certain situations elicit for certain people different responses than for others).

Early research interpreted interactions more in *statistical terms* as interactions in an ANOVA-type design with effects of persons, situations, and person × situation interactions. A concrete application is Endler and Hunt's (1966) S-R inventory: Using the example of anxiety, persons report how anxiety-inducing certain situations or stimuli (S) are and also record how likely or intense their anxious reactions or responses (R) to them would be. This creates a data structure where variance in anxious reactions can stem from the two main effects of persons (= individual differences in generally responding anxiously) and situations (= differences between situations in their general tendency to evoke anxious reactions) as well as the two-way interaction of person × situation (= unique

anxious reactions of specific persons to specific situations, beyond main effects). Typical results of such S-R inventories is that the variance of the person × situation interaction is quite sizable.

Other strands of research have also attended to person × situation interactions, such as educational (ATI; aptitude-by-treatment interactions), applied (TAT; Trait Activation Theory), clinical (diathesis-stress models), and behavior genetic literatures (gene-environment interactions). Particularly TAT may be seen as a modern spawn of interactional psychology because it posits that certain traits become activated only under certain situations which correspond to a significant interaction effect.

Person-Situation Transactions

The problem with the statistical view of person × situation interactions is that (a) B = f(P, E) cannot capture all the causal relations between persons, situations, and behavior and (b) the interaction term is conceptually blurry because it is all too often not clear what it means. The traditional ANOVA design models behavior as a dependent variable to be predicted from person and situation variables as independent variables. This could be seen as a one-sided approach because, as intended by Lewin, there are complex causal relations between persons, situations, and behavior. For example, Bandura captured them in his concept of causal or reciprocal determinism where persons, situations, and behaviors influence each other *bidirectionally* in all cases. More recent advances in personality psychology embody these principles, such as work on personality signatures and if-then patterns (Mischel & Shoda, 1995). Such approaches directly incorporate situations into the concept of a trait. Thus, a trait already denotes an interaction between the person and the situation because it is defined as an intra-individually stable pattern of "IF Situation X, THEN Response Y."

However, these approaches still do not address what exactly the interaction is and how it comes to be (i.e. how and why certain people are in certain situations and what they do to them). In other words, the mutual influence between persons and situations needs to be better understood. On a grand scale, there can be gene-environment transactions (Plomin et al., 1977). Gene-environment correlations can be passive (via parents an inherited genotype is correlated with the environment one is born into), evocative/reactive (genotype is correlated with certain reactions from others), and active (genotype is correlated with choosing and shaping certain environments). In contrast, gene-environment interactions occur when environmental effects on an outcome (e.g. delinquency) depend on the genotype and vice versa. Other researchers have focused on smaller scales: what people do to situations in their everyday lives (Ickes et al., 1997), which have been referred to as *situation management strategies* (Rauthmann & Sherman, 2016). Such strategies include maintenance (maintaining the situation as is), construal (uniquely perceiving or cognitively restructuring mental representations of the situation), evocation (usually unwillingly eliciting responses from others), selection (seeking or shunning certain situations), modification (actively changing an existing situation into something else), and creation (pro-actively generating an entirely new situation). The repeated utilization of such strategies may result in long-term developmental regulation and personality development (Caspi et al., 2005). To distinguish all of these mechanisms from statistical person × situation interactions, they are also referred to as *person-situation transactions* (Rauthmann & Sherman, 2016).

Summary: Meanings of "Person-Situation Interaction"

As summarized elsewhere (Lilienfeld et al., 2015; Olweus, 1977), a "person-situation interaction" can mean very different things, such as most commonly: (1) persons and situations both shape behavior; (2) relations between persons and situations are bidirectional (such that persons shape situations and situations shape persons); (3) persons and situations are interwoven in complex ways (which means that their effects on behavior cannot be separated properly); and (4) statistical effects of person variables depend on (i.e. are moderated by) situation variables and vice versa in the prediction of an outcome variable. Researchers should be aware of these meanings and ideally specify what exactly they mean.

Methodological-Statistical Considerations

To examine person × situation interactions or person-situation transactions, several methodological and statistical issues need to be taken into account. First, tracking person-situation transactions in the laboratory and in daily life requires intensive longitudinal data designs, such as experience sampling or ambulatory assessment. Second, large sample sizes are needed to reliably estimate robust person × situation interaction effects which can be relatively small in daily life (Sherman et al., 2015). Third, inherent in most research is the assumption that relations between persons and situations are linear. However, this need not be the case as effects can also be curvilinear so that non-linear interactions occur (see Schmitt et al., 2013). Lastly, the representativeness and/or comprehensiveness of persons, traits, situations, and behaviors sampled can influence whether and which interactions occur. Thus, great care must be taken to select appropriate variables and populations.

Researcher Biases

Zhipeng Gao

Simon Fraser University, Vancouver

Introduction

Researcher bias refers to researchers' tendency of having a partial perspective, which favors certain population or opinions against the alternatives. It is generally considered undesirable for two reasons. First, most psychologists are committed to producing objective knowledge, which provides an accurate description of people's personalities. Bias distorts knowledge and gives us an inaccurate idea about personality. Second, most psychologists wish their knowledge to be ethical and beneficial to society, whereas biased knowledge – for example, the statement that a particular population has a problematic disposition – can serve as a potent basis of discrimination and harm.

Researcher biases are usually caused when researchers unwittingly bring their personal characteristic, life experience, socio-cultural background, particular academic value, and so on, into personality research and arrive at biased research findings. In some cases, researcher biases are intentionally produced, such as in fraud research, but this entry primarily focuses on unintentional or implicit biases, which are more common and can be more difficult to avoid. This entry first introduces a few common biases, and then analyzes where they come from, before concluding with recommendations as how to reduce researcher biases.

Common Researcher Biases

Researcher bias may take place at various stages of research: selecting research topic, choosing theoretical/conceptual framework, establishing hypothesis, operationalizing variables, sampling, collecting data, data processing, interpreting data, report writing, publishing, etc. As researchers enjoy the flexibility to make decisions at all these stages, they may at the same time introduce biases into research. For instance, by testing one particular hypothesis, a researcher can be excluding other possible explanations in a biased way. Owing to space limitations, this entry only discusses a number of common biases.

Sampling bias refers to selective inclusion of individuals in research design so that the sample fails to represent the entire population. In convenient sampling, the researcher recruits participants who are easily available, e.g. family members, friends and colleagues of the researcher, to make up the participant pool, which is likely to resemble the researcher in terms of culture, socio-economic status, values, and so on, rather than representing people across society. Random sampling is often applied to overcome sampling bias. For example, in order to study the personality traits of students from one university, a researcher might select all students whose student ID ends with 5. In this way, students enrolled in this university are randomly selected, so that they are likely to represent all students in this university.

Another bias occurs concerning which groups of people are studied. It has been pointed out that psychological research participants are too heavily representative of the "weird" population – people who are Western, educated, and from industrialized, rich, and democratic countries (Henrich, Heine, & Norenzayan, 2010). When knowledge derived from this biased group is applied to other groups, it can lead to the evaluation of the other groups as deviating from the norm or can even be problematic by implication.

In other cases, marginalized groups, such as women, ethical/cultural minorities, LGBTQ, and people with low socio-economic status, are included in psychological research. However, their apparent differences from the average population are sometimes interpreted to be inferior or abnormal. Here bias takes the form of interpretation. Data do not speak for themselves, or in other words, any evidence must be interpreted in order to make sense. This is why in empirical research papers the result section is followed by a discussion section, which sheds light on what the data mean. And when interpreting data, researchers might introduce stereotypes or preconceived notions and arrive at biased conclusions. Ignorance of the possibility of biased interpretation can contribute to a naïve notion of evidence-based practice, because rather than directly determine practical intervention, evidence must be interpreted first. For example, symptoms of maladaptation do not necessarily suggest maladaptive personality traits to be treated; the problem can be possibly caused by social environment or relationship.

One very well-known bias is confirmation bias, which refers to the researcher's tendency of looking for and interpreting information in a way that confirms his/her existing expectations or beliefs (Nickerson, 1998). For example, with the expectation that one participant has certain personality traits, a researcher can make selective observation and interpretation of that participant's behavior to confirm his/her expectation.

Another common cognitive bias is the fundamental attribution error. According to this notion, people tend to explain human behaviors in terms of the internal characteristics of the actor, such as personality, instead of social contexts or situations. The fundamental attribution error signifies a dividing line between personality psychology and social psychology, namely whether we attribute participants' behavior to their personality or to their social context.

Researcher bias should be distinguished from biases caused by participants, theory, method, or language. For example, participants might produce a socially desirable report about themselves and thus bias the research findings. The concept of sex, previously used to explain the male/female difference, has been distinguished from gender, which emphasizes the social construction of women/men instead of their biological basis. Many methods and tests, such as convenient sampling mentioned above, have inherent

bias as well (Podsakoff, MacKenzie, Lee, & Podsakoff, 2003). It is important for researchers to become familiar with these types of biases as well, because researchers are the ones responsible for choosing theory, language, method, or influencing participants' response.

Possible Sources of Researcher Biases

In order to reduce researcher biases, it is necessary to understand where these biases come from. Certain instances of biases occur at the individual level, caused by one researcher's individual interest, motivation, attitude, cognitive process, identity, etc. In this case, biases committed by one researcher can be effectively avoided or caught by others. The famous psychologist Francis Galton received criticism for insisting that genius is inherited, and his bias can be attributed to his own extraordinary talentedness and eminent family background.

At other times, bias can be collectively shared. As hinted above, there has been a long history in which psychological research discriminated against women, ethnic minorities (Gould, 1996) and people with certain sexual orientations (Herek, Kimmel, Amaro, & Melton, 1991). Just as anybody else, psychologists are influenced by dominant ideologies about health, morality, gender, politics, etc., and when caught off guard, psychologists can reproduce these ideologies in their research findings. It should be noted, though, that conducting objective research does not necessarily require psychologists to give up their stances, which is unrealistic. Instead, it requires psychologists to be aware of their stances and prevent them from unconsciously biasing research.

Biases can hide in popularly shared research assumptions. For instance, classical psychoanalysis has been criticized for its overemphasis on the irrational aspects of human mind, behaviorism for its neglect of consciousness, neuropsychology for locating the cause of human behavior in the brain while ignoring social context. Researchers tend to treat their core research assumptions for granted, but a comparison among various schools suggests that their theoretical assumptions are prone to bias.

Biases can be caused by the academic structure in which researchers work. For instance, the "weird" population problem discussed above occurs because most psychologists conduct research in Western universities and have the easiest access to the "weird" population. In other situations biases stem from disciplinary or academic culture or convention. For example, journals tend to publish positive experimental findings – findings that are statistically significant and support the initial hypothesis. This bias is also called file drawer effect, because findings that do not support the hypothesis are less welcomed by publishers and often end up in researchers' filing cabinets. However, positive findings are not necessarily more valuable than negative findings, and the accumulation of file drawer effect can lead to serious misunderstanding of the topic being investigated.

Finally, financial ties may also create bias in research. For example, pharmaceutical companies can selectively support research projects that favor the production of lucrative drugs. Although most psychologists attempt to identify and avoid conflict of interest, sometimes they unintentionally take the stance of their employers. For example, in the famous Hawthorne studies, Mayo attributed labor conflict to workers' irrationality rather than the exploitive factory management and harsh work environment. Even with good intentions,

psychological research can be appropriated to advance the interest of the industry. In the early twentieth century, as employers were legally prevented from inquiring into job applicants' involvement with labor unions, they hired psychologists to screen out potentially disobedient job applicants with personality tests (Gibby & Zickar, 2008).

How to Reduce Researcher Biases

As mentioned above, researcher bias often occurs unintentionally or unconsciously; researchers commit bias precisely because they are not aware of how they are being biased. On other occasions, certain biases are shared across society or culture, so that researchers may take biased opinions for granted. Thus, bias is a ubiquitous phenomenon; it can be reduced but never fully eliminated. What principles can help personality psychologists to reduce researcher bias?

The prerequisite of reducing bias is that researchers recognize the undesirability of bias and are motivated to reduce it. This is easier said than done. It happens often that researchers believe their hypotheses are correct, or want their studies to be efficiently done and published, so that they manipulate experimental procedure, tweak data, and select from alternative theories, etc., to arrive at desired conclusions. Under pressure from tenure promotion or graduation requirements, researchers may hope the potential weakness in their quickly finished works will not be detected by academic peers. Self-criticism is painful, and biases may exist in research because researchers are less motivated to identify and overcome them.

Throughout history, psychologists have made persistent efforts to reduce biases through various means. Methods of controlling biases – such as operational definition and random sampling – are included in almost every introductory textbook and university training program. Double blind design, one of the most important experimental procedures, requires the experimenter to be unaware of which group the participants belong to, so that he/she cannot give away hints and influence the participants' response. Peer review, the standard publication procedure requiring scholarly submissions to be reviewed by academic peers before publishing, can be effective in identifying certain researcher biases.

However, these standardized methods cannot fully eliminate researcher biases. One common notion in popular culture is that scientific procedures are bias-proof, which is not true. For instance, peer review procedure is based on the assumption that one individual researcher's bias can be detected by another researcher. As manifest in the history of psychologists' discrimination against marginalized groups, when a certain bias is widely shared in society, the reviewer and author can both take the biased opinions for granted. In order to overcome this problem, researchers need to make persistent and creative efforts in addition to following the standard research design requirements against bias. In recent decades, psychologists have been urged to practice reflexivity – critical reflection on how one's experience, values, attitude, identity, social context, financial support, etc., may exert influence on psychological research (Finlay & Gough, 2003). Because each individual researcher, research design, and research context is different from another, researchers must improvise reflexivity in each case.

Cognitive and social psychological research has accumulated a wealth of findings on how human judgments can be biased, and psychologists themselves, as human beings after all, are not necessarily exempted from these biases in their research activities. If we bear

this lesson in mind, we can apply cognitive and social psychological findings to refine our research process. In social psychology there is a better-than-average effect, according to which most people think they are better than average of the rest of the population, which is statistically impossible. We can borrow this wisdom to inform our assessment of researcher bias – we are more biased than we are aware of. Or put another way, psychological knowledge, either produced by oneself or others, is less objective than it appears to be. Objectivity, the goal by which which most researchers attempt to reduce bias, can be approximated but never fully achieved.

Conceptualization

Conceptualization of the psychological unconscious, comprising of mental states and processes that are consciously inaccessible or unavailable, traces back to Freudian interpretations of the preconscious and unconscious minds as functioning outside of awareness or control. Although current understandings of unconscious processes in scientific psychology have moved beyond Freud's psychoanalytic framework, contemporary research continues to redefine the nature and scope of the unconscious mind, resulting in two distinct research paradigms. Historically, cognitive psychologists have focused on *subliminal* information processing, in which stimuli are presented below the threshold of consciousness, to study how, and to what extent, the unconscious mind is influenced by stimuli of which the perceiver is not consciously aware. Conversely, social and personality psychologists tend to focus on the individual's lack of awareness of the internal mental processes that influence thought and behavior. The key distinction is that the former domain is concerned with the influence of stimuli presented below the threshold of conscious awareness and the latter domain is concerned with the consequences of being unaware of the *effects* of stimuli, which can be presented subliminally or *supraliminally* (stimuli that can be consciously attended to) (see Bargh & Chartrand, 2000). Much of the research on individual differences in non-conscious processes has been conceptualized from this latter perspective, which draws heavily from methodological techniques that assess both temporary and chronic forms of concept accessibility.

Much of the research on the unconscious mind relies on the notion of concept accessibility, whereby people process objects and events within an existing mental framework, or *schema,* that can be activated outside of conscious awareness. *Accessibility* refers to the ease with which a schema is brought to mind and used to make judgments. That is, different people can perceive the world in different ways based on different mental models of the world that can stem from prior experiences or current motivational states. Thus, the same

situation or stimulus can result in different affective, cognitive, and behavioral outcomes as a function of individual differences in information processing that can occur outside of conscious awareness. Because frequently invoked information is thought to strengthen connections to related concepts in memory, exposure to repetitive or more salient stimuli can also result in their *chronic* or trait-like accessibility over time.

Techniques of Assessment

Priming techniques, in which certain information is activated in the mind, have been the dominant methodology used to assess how unconscious mental processes account for the effects of various stimuli on affect, cognition, and behavior. These techniques rely on differences in speed of participant responses (reaction times), target judgments, and behavioral responses to capture individual differences in information processing (e.g. rejection sensitivity).

Psychological research on automaticity has revealed that individual differences in knowledge structures that are chronically accessible in memory, due to past experiences, can differentially impact the ways in which people respond to temporarily activated concepts. For instance, research on rejection sensitivity – an individual difference variable that captures chronic tendencies to expect, perceive, and overreact to social rejection – has shown that temporary exposure to relationship-relevant stimuli, such as an upcoming anniversary, predicts partner judgments (e.g. perceptions that one's partner is faithful) among individuals with higher levels of rejection sensitivity.

Among the most common techniques used in priming and automaticity research are conceptual priming, mindset priming, and sequential priming methods. Conceptual priming techniques refer to the activation of a particular mental representation in one context that influences responses in a subsequent, unrelated context. For example, the scrambled sentence test – in which participants have to construct a series of four-word sentences when given five word options in which one of the words, unbeknownst to the participant, constitutes the prime – has been used to temporarily activate concepts such as "patience" or "rudeness" outside of awareness. In one study, participants who were primed with the concept of patience were significantly less likely to interrupt an experimenter compared to participants who were primed with the concept of rudeness. The related technique of mindset priming has been used to explore individual differences in goal-directed cognitions. In this paradigm, participants may read a scenario describing someone who is displaying a certain trait, such as hostility, and the primed trait – a mindset prime – which can subsequently influence how participants perceive others in an ostensibly unrelated impression formation task.

The sequential priming technique has been used to test relatively stable relationships between concepts to measure individual differences in their chronic accessibility. For instance, a lexical decision task, in which participants decide whether or not a target letter string is a word or a non-word, can be used to assess response latencies for target concepts (e.g. doctor) following relevant (e.g. nurse) and irrelevant (e.g. toast) primes presented subliminally. Shorter latencies are posited to reflect automatic associations in the unconscious mind – in this case, between the concept of nurse and doctor. Another sequential priming task, the Affect Misattribution Procedure (AMP), has been used to

assess individual differences in unconscious, or *implicit*, attitudes. In this task, participants are asked to rate the pleasantness of various abstract patterns, such as Chinese characters, following a stimulus prime. In an experiment on alcohol attitudes and consumption, the pleasantness ratings of pictographs following alcohol-related images (compared to water-related images) were positively associated with higher rates of self-reported alcohol consumption (Payne, Govorun, & Arbuckle, 2008).

What these techniques have in common is the activation of mental representations that have residual effects on later tasks or responses, an influence that participants may be unlikely or unable to consciously recognize and report. Consequently, these residual effects are considered to be unconscious or implicit processes because people lack awareness of and intentionality behind the cause of their actions, which are the two primary features that have been used to distinguish between conscious and unconscious processes.

One of the most popular techniques for assessing implicit attitudes is the Implicit Association Test (IAT; Greenwald, McGhee, & Schwartz, 1998). In the traditional IAT, stimulus words or images are presented sequentially that represent two target categories (e.g. self vs. others) that are paired with bipolar attributes (e.g. good vs. bad) using the same two response keys. Faster responses on the IAT are thought to reflect stronger automatic associations between paired concepts (e.g. "self" and "good") compared to an alternative pairing (e.g. "self" and "bad"). The IAT has been used to quantify the strength of different associations that have developed over time through repeated exposure and are presumed to reflect relatively stable differences in individual attitudes. For example, studies using the Race-IAT, which pairs positive and negative attributes with the racial categories Black and White, has shown that a majority of White participants in the United States demonstrate an implicit preference for Whites over Blacks, whereas roughly half of Black participants show an implicit preference for Blacks over Whites. Implicit measures such as the Race-IAT have been used extensively to assess a wide range of attitudes that individuals may be unable or unwilling to report, due to a lack of insight or concerns about appearing prejudiced, or conflicting conscious (self-reported) egalitarian attitudes.

The decision to use priming techniques versus a double categorization task, such as the IAT, when investigating individual differences depends on the outcome of interest. For instance, whereas priming techniques have been shown to be stronger predictors of target judgments of a single exemplar of a given category (e.g. a single Black celebrity), the IAT is a stronger predictor of evaluations made at the category level (e.g. stereotypes of Black people). Thus, individual differences in racial or ethnic group preferences (e.g. Japanese Americans vs. Korean Americans) may be better captured using the IAT, whereas judgments of individual members of a particular racial or ethnic group may be better captured using a sequential priming task.

Methodological Issues

Studies that use priming methods and that include serial tasks should be carefully constructed to conceal the relation between stimulus prime and the task by, for instance, using different rooms for administering different tasks or using multiple experimenters, when possible. When stimulus primes can be consciously detected (as is the case in many

of the aforementioned priming tasks), it is critical to engage in a comprehensive debriefing procedure, commonly referred to as a "funneled debriefing," to ensure that participants are not aware of the relation between the priming task and the particular outcome of interest. In this procedure, researchers may ask participants a series of open-ended questions to assess participants' beliefs about the purpose of the experiment, if they noticed particular relations between the tasks, and if they were aware of particular strategies they used when completing the tasks (see Bargh & Chartrand, 2000).

Subliminal priming methods can be used to help circumvent socially desirable responding or the influence of other demand characteristics that may arise through the use of supraliminal priming techniques. Moreover, demonstrating an effect using stimuli presented at speeds too fast to consciously detect increases confidence that unconscious processes are driving the observed effect. Additionally, pattern masks presented after subliminally presented stimuli can further mitigate conscious detection of stimulus primes.

Additional support for the operation of unconscious processes can be established through the use of a cognitive load manipulation in which participants are given a concurrent task to complete that relies on working memory. Generally, interference from cognitive load is expected for conscious processes but not for unconscious processes. If response latencies are unaffected by a given load induction (e.g. remembering an eight-digit number while performing a concurrent task) unconscious processing can be better inferred because substantial cognitive resources were not required for completion of the task.

Finally, in some cases, effects of subliminal primes may be weaker or more difficult to detect compared to supraliminal primes. The duration and intensity of subliminally presented stimuli can be increased to better detect or strengthen an observed effect, however, awareness checks should be conducted at the end of an experiment in order to ensure that participants are unaware of the particular features of the prime presented.

Cognitive Methods in Personality Research

Damaris Aschwanden[1], Mathias Allemand[2], and Patrick L. Hill[3]

[1] *Florida State University*
[2] *University of Zurich*
[3] *Washington University in St, Louis*

Mental abilities and cognitive processes are key competences that are needed to meet the challenges of job and family demands, education and advanced training, societal expectations, and to manage the demands of everyday life. However, individuals differ with respect to cognitive processes and performance (cf. Matthews, 2009). Therefore, it is of interest for personality research to study how, when, and why individuals differ in cognitive processes and performance. To be more specific, individuals who are interested in reading activities might read more often than individuals who do not like books and newspapers, resulting in different reading skills. On the between-subjects level, previous research found associations between cognitive abilities and the Big Five personality traits, mainly for openness to experience, neuroticism, and conscientiousness (e.g. Ackerman & Heggestad, 1997; Luchetti, Terracciano, Stephan, & Sutin, 2016). Openness and conscientiousness are usually positively related to cognitive functioning, whereas neuroticism is negatively associated with cognitive functioning. Particularly, individuals who are more open to experience will be predisposed to think more creatively, to seek new ideas, and to engage actively in cognitively stimulating activities across different life domains. Consequently, an intellectual active lifestyle will positively influence the maintenance of higher cognitive functioning. Likewise, conscientious individuals may engage in various health behaviors that are protective against age-related changes in the brain. On the contrary, neurotic individuals are characteristically more anxious and prone to intrusive thinking as well as distraction, which could impede their ability to focus on a cognitive performance task (cf. Graham & Lachman, 2012). However, little is known about the mechanisms that underlie the link between cognitive processes and personality traits. Future research needs to shed light on the underlying associations between cognition and personality.

The primary aim of using cognitive methods in personality research is to examine the processes that transpire in real-time transactions with the environment. In contrast, self- and observer-reports seek to capture generalizations that individuals make about

themselves and others. Cognitive and self-report methods may or may not correspond with each other. For example, research has shown that Implicit Association Tests (IATs) predicted spontaneous Big Five behavior, but explicit measures did not. In contrast, explicit measures, but not IATs, were related to self-rating of behavior (Steffens & Schulze-König, 2006). Furthermore, traditional personality research methods such as self-reports fail to capture many of the cognitive processes that transpire when individuals are exposed to stimuli, because individuals do not have conscious access to how they process stimuli in real time. Thus, individuals are not able to report on these processes (Robinson, 2004). Moreover, self-reports rely on subjectivity and retrospection. By contrast, cognitive processes can be measured both in an objective (e.g. cognitive tests) and subjective way (e.g. self-reports of cognitive processes). Though self-reports measures of personality show predictive validity for important life outcomes (Roberts, Kuncel, Shiner, Caspi, & Goldberg, 2007), there are important reasons to use cognitive measures in personality research. Researchers commonly discuss personality traits as constellations of thoughts, feelings, and behaviors (cf. Roberts, 2009). However, most research on personality traits has focused solely on how they relate to behaviors and emotions. As such, there is a need for additional research on the cognitive signature of personality traits. Investigations along this front will be inherently valuable not only for advancing the scientific understanding of given traits, but also for helping to explain the reasons why personality traits appear to hold such consistent effects on important life outcomes. In other words, personality research using cognitive methods can elucidate the mechanisms linking personality traits to well-being and success across life domains.

Defining Cognitive Processes

For this chapter, five cognitive processes that are important for personality research are discussed (cf. Robinson, 2007): (1) *Accessibility* is defined by the speed or ease with which an individual can place an object (e.g. cat) in a relevant category (e.g. animal), it is a pre-activation of a concept. (2) *Attention* is defined as the selective narrowing or focusing of awareness to specific stimuli/information. (3) *Executive functions* is an umbrella term for the complex cognitive processes that serve goal-directed behaviors by updating, shifting, and inhibiting information. (4) *Implicit self-attitudes* are defined as subliminal attitudes and self-concepts about the self. They are unconscious but manifested in behavior. (5) *Semantic priming* is defined as using a semantic stimulus to sensitize the accessibility to a later presentation of the same or a similar stimulus. The term semantics refers to established knowledge about facts, objects, and word meanings. Semantic memory networks organize memory material, but they are invisible and unconscious.

Measuring Cognitive Processes

Cognitive processes can be measured implicitly or explicitly. In implicit methods, it is not obvious what is being measured. In contrast, it is to some extent obvious what is being measured in explicit methods. In addition, cognitive methods are typically used to assess

(1) the *maximal performance* of an individual or (2) *typical cognitive processes and functioning* in daily life. Maximal performance can be measured using *power tasks* that increase in difficulty or *speed tasks* that need to be executed as fast and accurately as possible. In the next section, cognitive task examples of measuring selected personality aspects are given. However, it is important to note that these tasks could be employed to study a wide array of personality traits.

Accessibility can be assessed using a choice reaction time task in which individuals are asked to decide whether a word belongs to one category or another as fast and accurately as possible. The speed of categorizing words is taken as an indicator of the accessibility of the targeted construct. Thus, an individual will be fast when the targeted construct is more readily accessible. By contrast, inaccessible constructs would produce marked difficulties with the task and result in slower speed. For example, accessibility can be linked to the individual differences in blame. In the blame categorization task, individuals are asked to classify words as blameworthy or not as fast and accurately as possible. Previous research has shown that an individual who frequently assigns blame in everyday life is relatively quick at categorizing blameworthy words as compared to an individual who does not frequently assign blame in everyday life (Meier & Robinson, 2004).

Selective attention tasks are used to investigate individual differences in traits, such as anxiety and threat. For example, two words are simultaneously presented, one being threatening in nature (e.g. spider), and one being non-threatening in nature (e.g. chair). Individuals are told to attend to the words generally, and after some delay, the words disappear. Then, a spatial probe replaces one of the two words, simply requiring detection (e.g. "hit the space bar as soon as you detect X"). Previous research demonstrated that if individuals react faster to the spatial probe when it occurs in the location of threatening words, then the individual was preferentially attending to them. This means covert attention to threatening or nonthreatening words can be detected (cf. Robinson, 2007).

Executive functions are typically assessed with paradigms such as the Stroop task (Stroop, 1992) in which individuals are asked to provide the font color of the word displayed on the screen. This becomes more difficult when the text of the word conflicts with the font color (e.g. the word "green" written in blue) – or when the word is of greater personal relevance. In other words, when the word means something to the viewer (e.g. the viewer's name, a central personal characteristic), it can affect the viewer's attention and shortly distract him or her from the color-naming task. For example, executive functions can be linked to individual differences in trait anxiety. Indeed, previous research has found that individuals high on trait anxiety show a greater attentional bias toward anxiety-related words such as criticism compared to those individuals low on trait anxiety (cf. Robinson & Neighbors, 2006).

Implicit self-attitudes are typically assessed with two procedures, namely the alphabetic letter evaluations and the Implicit Association Test (Greenwald, McGhee, & Schwartz, 1998). The underlying idea of the first procedure is that individuals with positive attitudes toward the self will prefer the letters which appear in their names. The IAT consists of two choice reaction time distinctions. This can be illustrated briefly by an example measuring self-esteem (Greenwald & Farnham, 2000): One choice reaction time distinction refers to the distinction between self (e.g. the word *me*) and other (e.g. the word *them*), and one refers to the distinction between pleasant (e.g. the word *holidays*) and unpleasant (e.g. the

word *pain*). Individuals are asked to perform two combined blocks. In the first block, self and pleasant words are associated with one response key; similarly, other and unpleasant words are associated with one response key. In the second block, these mappings are reversed. The difference between the speed in the self or pleasant block and the self or unpleasant block is then defined as the IAT self-esteem (higher scores indicate higher levels of implicit self-esteem).

Semantic priming is typically assessed with the primed lexical decision task. Individuals are told to categorize letter strings as words or non-words. Individuals are briefly flashed with a prime word shortly before the presentation of the target letter strings. Lexical decisions are faster, when primes and targets are related (e.g. emotion – anger) versus unrelated (food – anger). Regarding attachment theory, stress-related primes (e.g., death) can activate proximity-seeking thoughts (e.g., love) in secure and anxious, but not in avoidant individuals (Mikulincer, Birnbaum, Woddis, & Nachmias, 2000).

Integrating of Personality and Cognitive Processes

The use of cognitive methods has considerable value to understand individual differences in personality processes and traits. However, it is unlikely that any cognitive measure can entirely tap a personality trait, because cognitive processes are dynamic in nature. In contrast, personality traits are relatively stable across various situations and contexts. Therefore, it is important to distinguish between micro-levels (e.g. milliseconds) and macro-levels (e.g. working memory performance) of cognitive psychology. Looking at the micro-level may provide valuable insights into personality states, whereas looking at the macro-level may provide valuable insights into personality traits. Likewise, it is important to consider reliability and validity when choosing one's cognitive method for a specific research question in personality psychology. The use of cognitive methods makes a unique contribution to personality research, for example when (1) it comes to potential cognitive mechanisms that are involved in trait-outcome relations; (2) important information cannot be examined by self-reports or behavior observations; and (3) cognitive processes may act as a moderator of trait-outcome relations. With regard to personality research studying individual differences in cognitive processes, it may be useful to widen the scope of investigation by taking third variables such as intellectual engagement or interests into account. It might be that such variables act as mediators or moderators of the relationship between cognition and personality. For example, individuals who enjoy intellectually demanding activities, which involve abstract thinking and problem solving as well as reading, may be more open and show higher scores in problem-solving tasks. Thus, it may be possible that intellectual engagement mediates the relationship between openness and problem-solving abilities.

Using cognitive methods in personality research certainly promotes a greater integration of cognitive and personality psychology where both areas can benefit from. For personality psychology, the traditional methods repertoire of self-reports and behavioral observations is expanded by cognitive methods. For cognitive psychology, a better understanding of personality differences in cognitive performance can help to develop cognitive trainings and interventions based on these personality differences.

Experimental Approaches

Sameen Boparai[1], Kajung Hong[2], and Jessica L. Borelli[3]

[1] *University of Washington*
[2] *San Diego State University/University of California, San Diego*
[3] *University of California, Irvine*

Defining the Experimental Approach

Researchers conduct an experiment by examining how a manipulation (*independent variable*; *IV*, predictor variables, explanatory variables) affects certain outcomes (*dependent variable*; *DV*) in a controlled setting. By accounting for the effects of external factors that are not relevant to the association under investigation, researchers are able to infer a causal relation between the independent and dependent variables. In contrast, observational studies only allow researchers to infer non-directional associations due to the lack of control over extraneous variables.

Experimental Design

Experiments involve one or more levels of the independent variable, called e*xperimental conditions,* and a *control condition*, which provides a basis for comparison with the experimental manipulation. Some researchers also investigate the combined effects of multiple independent variables through a *factorial design*, in which the dependent variable is measured at all possible combinations of the different levels of the independent variables. To illustrate, consider a study of the combined effects of a stressor and caffeine on participants' cortisol levels; this would involve a 2X2 factorial design with four conditions involving either caffeine or a placebo and a stressful or neutral task.

Experimental designs can also be divided into between-subjects and within-subjects experiments. Participants in between-subjects experiments are randomly assigned to an experimental or control condition, while participants in within-subject experiments receive all levels of the independent variable, including the control condition. A between-subjects design reduces the possibility of participant bias, as participants are unaware of the other experimental conditions. When participants are aware of the experimental

conditions, as in the case of within-subject experiments, they may alter their behaviors consciously or unconsciously, resulting in demand characteristics. However, within-subjects experiments ensure that there are no pre-existing individual differences between the experimental and control groups that could affect the study findings. In addition, fewer participants are needed for a within-subjects study, as the participants do not need to be divided into groups.

Experimental Control

To rule out alternative explanations for the observed effects in an experiment, researchers control for extraneous variables that could affect the study outcome. Factors that randomly affect the measure outcomes, such as participant mood, are sources of random error. These factors increase the variability of the data, but do not influence the overall relation between the variables. If a factor varies systematically with both the independent and dependent variables, it is a confounding variable that must be controlled through the experimental design or during statistical analysis in order to isolate the effect of the independent variable. For example, one possible confound in the previously mentioned study on the effects of a stressor on cortisol levels would be the time of day, as cortisol levels vary diurnally. To control for this effect, researchers could conduct experiments at the same time of day.

Different tactics that researchers employ to reduce confounds include random assignment to condition, standardization of the study procedure, counterbalancing, and a well-designed control condition. Participants are randomly assigned to their conditions to reduce systematic differences between the characteristics of the participants in different groups. Thus, differences between the groups prior to the experimental manipulation are due to chance and differences following the manipulation can be attributed to the independent variable with greater confidence. The most straightforward method of random assignment is simple randomization, in which each participant is randomly assigned to a group, often through a random number generator. If researchers wish to have greater control over the composition of the different groups, they may use block randomization, in which participants are separated into groups, or "blocks," based on certain characteristics that the researchers wish to keep consistent between the conditions, such as gender. Participants in these blocks are assigned such that there are a certain number from each block in each condition.

Additionally, researchers standardize the study procedure by providing the same experience for all participants so that there is no meaningful variance in the manner in which the data is collected. Participants in the control group must be treated as equally as possible to those in the experimental group(s), with the exception of the factor of interest (IV), to ensure that the findings cannot be attributed to unrelated aspects of the manipulation. To prevent the order of the study tasks from affecting the study findings, researchers are advised to *counterbalance* or randomize the task order. If it is not possible to control for certain confounds through the experimental design (e.g. age or gender), researchers may statistically control for them by measuring the confounds during the experiment and then including them as covariates during data analysis.

Reliability and Validity

In addition to isolating the relation between variables in a study, researchers must also determine whether these variables are accurate and generalizable representations of the constructs that they are attempting to measure. The measured variables in a study are used as indicators of unobserved latent constructs, such as extraversion or self-esteem. In order to test the degree to which measured variables reflect their intended latent constructs, researchers assess the reliability (see Reliability, Issues of) and validity (see Validity, Issues of) of measures. Reliability refers to the extent to which a measure yields consistent and stable results provided that the underlying construct does not change, while validity refers to the degree that a measure captures the construct that it was intended to measure. Additionally, the validity of a study as a whole indicates how well the study examines the relation between the latent constructs. Internal validity is the confidence that a study's findings were caused by the experimental manipulation, ruling out other possible explanations. The use of experimental control increases the internal validity of a study. External validity is the generalizability of a study's findings to a larger population in a real-world environment. To increase external validity, the study sample should ideally be a random sample of the population that the researchers wish to generalize to so that the characteristics of the study sample do not differ substantially from the characteristics of the target population.

Ensuring the Integrity of the Experimental Manipulation

In some experimental designs, the independent variable is a construct that is manipulated indirectly, such as emotional state. To make sure that the independent variable is successfully manipulated in an experiment, researchers perform manipulation checks. These can take the form of a direct question at the end of experiment (e.g. "To what extent did you find the task stressful?"), a self-reported questionnaire that examines one's state before and after the manipulation, or changes in physiological measures, such as heart rate or cortisol. Manipulation checks are particularly useful for providing possible explanations when findings do not emerge as expected. If a manipulation check indicates that the independent variable was successfully manipulated, but the changes in dependent variable are not in line with expectations, researchers can infer that there is no causal relation in the hypothesized direction. However, if the manipulation check is not successful, researchers may revise the experimental manipulation to test the hypothesis more effectively in future studies.

Quasi-experiments

Quasi-experiments differ from experiments in that participants are not randomly assigned to conditions. This method is easier to implement than experiments, especially in intervention research, as it makes use of pre-existing groups within the sample. Two major types of quasi-experimental designs include non-equivalent groups and regression-discontinuity. A non-equivalent groups design involves researchers assigning intact groups, such as neighborhoods with similar demographics or classrooms, into different conditions (e.g. testing an intervention

in two schools, where one is the control group), while a regression-discontinuity design involves researchers assigning participants to groups on the basis of a cut-off score measured prior to the intervention (e.g. testing an intervention for children who report high risk for psychopathology). Quasi-experiments are used when it is impossible or highly inconvenient to randomly separate participants into groups. For example, when studying the effects of a manipulation on drug users, it would be unethical to randomly assign participants to use harmful drugs. Since participants are not randomly assigned to their condition, quasi-experiments have lower internal validity, as there may be systematic differences between the experimental and control group prior to the manipulation. Due to the possible influence of confounding variables, identifying a causal link between the independent and dependent variables is not possible.

Experiments in Personality Research

Personality researchers use an experimental approach to examine how personality traits (also known as person variables), the consistent characteristics of one's moods, thoughts and actions, interact with contextual factors and experimental manipulations to affect participants' current state. For instance, one study asked participants to report on their personality traits and randomly assigned them to conditions that induced either positive, negative, or neutral affect, measuring their susceptibility to these emotional states (Larsen & Ketelaar, 1991). The findings revealed a link between extraversion and susceptibility to positive affect as well as between neuroticism and susceptibility to negative affect. While this study randomly assigned participants to conditions designed to affect their current states, researchers may also use a quasi-experimental method to separate participants into conditions based on their levels of a personality trait, such as comparing the effects of a manipulation on individuals who report high or low aggression.

Analysis of Experimental Data

Researchers analyze experimental data by looking at differences between the means of the experimental and control groups. Certain statistical tests, such as *t*-tests and *F*-tests, reveal the significance of differences between conditions based on the resulting *p*-value, a measure of the possibility that the study findings would occur by chance. If there is less than a 5% possibility that the findings would randomly occur (i.e. $p < 0.05$), the finding is considered to be statistically significant. It is also important to understand the magnitude of group differences by examining their effect size, commonly measured through Cohen's *d* (Sullivan & Feinn, 2012). Researchers are advised to report on the size and consistency of effects in addition to significance, particularly as statistical significance varies as a function of sample size.

When interpreting the findings of experimental data, researchers must also consider their generalizability, which is affected by the limitations of the sample as well as the artificial nature of the experimental setting and manipulation. Further, since many studies examine personality traits through the lens of a specific task, the findings cannot be generalized to all situations and replication (see Replication Research) is needed to determine the external validity of the findings.

Strengths and Limitations

Well-designed experimental studies are higher in internal validity than observational research, which allows researchers to draw strong causal inferences from their findings through the use of control, random sampling, and random assignment to condition. These inferences are particularly important in building scientific models in personality research, enabling researchers to refine theories by disconfirming alternative explanations.

However, experiments can be difficult to administer, as they require rigorous planning. Additionally, the findings from experiments may not be generalizeable outside of a laboratory setting. Participants may act unnaturally because they are aware of being observed, which is referred to as participant reactivity, or may display demand characteristics, modifying their behavior based on their assumptions of the experiment's expected outcomes. Furthermore, the method may lack ecological validity if the manipulation strays too far from possible real-world situations. Despite these limitations, the experimental approach allows personality researchers to test existing theories to understand individual differences as well as general central tendencies.

Historiometry

Constance A. Sztukowski-Crowley[1] and Dallas R. Funk[2]

[1] *Port St. Lucie, FL*
[2] *Indianola, IA*

Brief Overview

Historiometry, or historiometrics, is the use of statistical analyses to examine human behavior through the lens of historical individuals. According to Simonton (2015), it was Frederick A.Woods who first coined the term in 1909, saying that historiometry is the group of investigations where "the facts of history of a personal nature have been subjected to a statistical analysis by some more or less objective method." A more precise definition, however, was drafted by Simonton in 1990: "Historiometrics is a scientific discipline in which nomothetic hypotheses about human behavior are tested by applying quantitative analyses to data concerning historical individuals."

This definition is composed of three key elements: the nomothetic hypotheses, the quantitative analyses, and historic individuals. A nomothetic hypothesis is one in which specifics have been removed in an effort to search for general laws and traits where the research produces statistically significant results. In the case of historiometrics, the results take the form of a statistical association such as a correlation coefficient and allow the researcher to create predictions about people in general.

The second element of historiometric research is quantitative analysis. In order to achieve this, the variables being examined must be quantified on some numerical scale and directly address the hypothesis. By its very nature, quantitative analysis looks at variables to help establish relationships between them and allows for a generalized finding, which is precisely what historiometric research is attempting to do. The nomothetic hypotheses provides the starting point for the research, and the quantitative analysis provides the statistical results that are either a confirmation or a falsification of the nomothetic hypothesis.

Another important element of Simonton's definition is the use of historic individuals as the sample of choice for the research. Historic individuals are those who have left a mark on civilization. They may have made a name for themselves by being leaders, geniuses, exceptional creators, or notable talents. Simonton (1999) referred to this type of subject as

"significant samples." These significant samples may provide opportunity to demonstrate the generalizability of findings from traditional methods and samples. They may also be used because they are representative of the extreme upper end of the normal distribution of human traits.

Historiometry tries to identify the characteristics that enable these exemplars to achieve and become timelessly impactful.

It is important to note that "historic individuals" does not actually mean limited to specific individuals. Events, products, military decisions, or even aggregates of historical individuals (referred to as generations) may be the sample focused upon for this type of research. Whatever the sample, all personal details are stripped including the individuals' names. A figure that is included in the sample will simply be identified as a number, rather than a person, allowing the famous to remain anonymous. Because of this, researchers are able to use living subjects with a contemporary application, rather than just subjects from past eras. This allows for a maximum amount of cultural and historical variability, with a larger probability for statistically significant universal laws and traits.

In order for this definition of historiometry to be useful, however, there are two key assumptions that must be made. First, an historical person matters. That is to say, one individual can and does make a difference, having a crucial, causal role in events. This philosophy is often associated with the great person theory of history, which dates back to ancient philosophers such as Plutarch, and deals with the notion that great people do not ride the waves, but are instead "a force that makes new waves" (Simonton, 2015, p. 185).

The second assumption is that history repeats itself in a regular enough pattern that you can create broad generalizations that have been stripped of their historic particulars. This goes along with philosophers who believe that history is a series of events that create a pattern transcending nations, time, and civilizations. Both of these assumptions are independent of each other; without either of them, historiometric research would not be able to maintain its nomothetic, generalized approach and results. Consequently, historiometry operates on the ideas that laws exist to explain how individuals can leave a mark on history, and that the individual's attributes, thoughts, and traits do contribute to collective history.

History

Historiometry as a method was first named and defined by Frederick A. Woods in 1909 when he created a bibliography that listed historiometric researchers, starting with Francis Galton's 1869 study *Hereditary Genius: An Inquiry into Its Laws and Consequences*, which is most notable for being the first historiometric inquiry to apply the Pearson product-moment correlation coefficient. Woods also wrote several historiometric studies himself, the first in 1906 when he wrote a study called *Mental and Moral Heredity in Royalty: A Study in History and Psychology*. In 1911 he wrote *Historiometry as an Exact Science*, where he wrote about his belief that historiometry would "solve" fundamental questions of history, such as why nations rise and fall, and what creates a genius leader. Finally, in 1913, he wrote his last study, *The Influence of Monarchs: Steps in a New Science of History*, where he contended

that personal qualities of the head of state have definite repercussions for the welfare of the nation as a whole.

Simonton later made his own list of notable historiometric research, including a study that Woods had missed, and thus failed to include in his 1909 bibliography, as well as studies which have occurred since Woods was active. According to Simonton, the earliest historiometric study was Adolphe Quételet's 1835 study: *A Treatise on Man and the Development of his Faculties*. This was the very first empirical study of relationship between creative output and historical age and is the first known historiometric investigation.

Other notable historiometric examples include James McKeen Cattell's 1903 study ranking the 1,000 most eminent persons in history – including those in science, art, politics, religion, and the military – measuring the level of their eminence according to the amount of space each subject took up in standard reference books. There was a notable study in 1904 by Havelock Ellis, in 1917 by Lewis M. Terman, and in both 1936 and 1950 by Edward Thorndike.

Lewis M. Terman also wrote a five-volume longitudinal study of gifted children followed through to adulthood called *Genetic Studies of Genius*, which went from 1929 through 1959. A final notable example is Catharine Cox's 1926 *Early Mental Traits of 300 Geniuses*. This is the single most ambitious historiometric study ever, and was the first to use partial correlation and the reliability coefficient. Cox began her study by taking Cattell's list of 1,000 eminent historical individuals. She then deleted the bottom half and eliminated hereditary monarchs and those born before 1450, leaving her with a total of 301 individuals in her sample.

Finally, Cox and her team of researchers used biographical data to rate the individuals on two IQ measures and then calculated the correlation between each individual's IQ and their ranked eminence. She took her study even further and examined the character traits of a subset of 100 individuals and determined that characteristics of motivation, such as energy, persistence, and determination, are more critical to success than even the highest IQ.

Application

Historiometry provides a very specific approach to research that cannot be achieved by alternative methods. Take, for example, the idea that highly successful, creative individuals tend to struggle with depression and mental disorders. In order to do a laboratory study on the hypothesis that these two variables are connected, a researcher would need to get past the ethical objections surrounding the idea of deliberately influencing a person's mental health and then find a method with which to do just that, followed by measuring in some way their level of eminence after the fact.

If you went with a more correlational approach, which is what is implied by the very question suggested in this example, the researcher would need to find creative individuals that are both struggling with depression or a mental disorder and have achieved a high-level of success. The usual subjects used for such correlational studies – college students, random survey participants picked off the street or through internet forums – are by their very nature not likely to have achieved a high level of success and therefore would not qualify for this specific study. Traditional methods present issues that must be overcome in

order to examine the type of nomothetic hypotheses that will help us understand the patterns of history and the unique characteristics of these significant samples. The primary difficulties researchers are faced with are, first, that the subject may be too famous to easily allow study. Even if available for study, the subject may be averse to psychological inquiry. Additionally, when we consider the pool of notable talents throughout history, many are now deceased and can only be considered at a distance.

Historiometric research addresses all of these problems. By using people who already exist – or existed in the past – the research by-passes the need to find a method to influence the mental health of a creative individual and also avoids the corresponding ethical objections. It allows not only for the use of living, contemporary individuals, but historical ones as well, allowing for a much larger sample size all the way around: *any* civilization, nation, or time period is opened up to the researchers. The greater the timespan, the more valid the resulting generalized laws or traits. Historiometric researchers come from many fields. Some, but certainly not limited to these fields, are the following: cognitive psychology, developmental psychology, differential psychology, and social psychology. Within the cognitive field, a researcher could examine, for example, either the creative process or the decision-making process. Developmental psychologists could use historiometrics to study the impact of genetic or environmental factors, career trajectories, or even life expectancies. Within the field of differential psychology a historiometric study could examine traits such as productivity, intelligence, openness to experience, motivation, and psychopathology. Finally, a social psychologist could use historiometry to study gender effects, social networks, group dynamics, leadership, socio-cultural context, and even the phenomenon of multiple discoveries (when more than one person comes up with a new idea or the same idea).

It is important to keep in mind, however, that not all research subjects or researchers are suited to historiometry. Many psychology concepts cannot be studied via historiometry. Historiometrics, after all, deals only with the intersection of history and psychology: when psychological questions demand the inclusion of historical individuals, events, or generations. It is also critical to remember that historiometrics is labor intensive. While the world of technology – most notably the advent of the internet and the laptop – has made the gathering of data more accessible, it still takes a great deal of effort to find, sift through, and analyze the variables necessary to create the database required of a historical correlational study of the magnitude engendered by historiometry. While historiometry is still relatively young, at least as far as the number of historiometric studies that have been completed, it has a lot of unique offerings for the field of psychology, with plenty of room for future growth.

Internet Research in Personality

Feng Ji and Eros R. DeSouza

Illinois State University

Psychological science is experiencing a "reproducible crisis" or deficiency of replicability of findings, hampering the generalizability of the findings. The internet now plays an important role in nearly 40% of the world population that uses it in everyday life (Int. Telecommunication Union, 2015). Thus, it provides researchers with a new way to recruit a vast spectrum of participants and in real-world conditions across the globe, helping personality findings become truly generalizable. In this entry, we provide an overview of the current internet-based research in personality.

Internet-based Methods in Personality Research

Online Study Platform

Traditional paper-and-pencil assessments and laboratory-based behavioral experiments can easily be converted into online surveys and online experiments, respectively, without having to be knowledgeable about web-setting and programming. All researchers need is to use point-and-click interface to set up their own surveys/experiments and make the web link available to research participants.

Crowdsourcing Sites

With the advent of crowdsourcing sites, e.g. Amazon Mechanical Turk (MTurk), researchers have even more convenient ways to recruit targeted participants at a very low cost. Researchers simply post requirements for participation and financial compensation online. Initially, researchers had some concerns about the validity and reliability of the data gathered through MTurk. However, Buhrmester, Kwang, and Gosling (2011) rebutted such concerns. They showed that MTurk is a reliable research tool, producing high-quality replicable data.

Manipulation Checks

The quality of data collected online can be enhanced by applying manipulation checks. Oppenheimer, Meyvis, and Davidenko (2009) discussed how participants can complete attention-checking items, which have superficial resemblance to other items; however, if participants are inattentive, they will likely answer these "mock" items incorrectly. Researchers can also delete participants who have taken too much or too little time to finish experiments, or delete repeated attendances by examining IPs and so on.

Big Data and Social Network Sites

For the first time in the history of humanity, whole populations are accessible for research through large data sets (big data) obtained through the internet. Thus, big data and data science – an interdisciplinary domain in which techniques from multiple disciplines (e.g. statistics and computer science) – are utilized to predict and explain behavior (Dhar, 2012).

Social Network Sites (SNS)

SNS and new data-mining technology allow analysis of users' online everyday interactions, bringing new opportunities and challenges (e.g. privacy and ethical issues). Computer science and data science technology allow researchers to access internet users' footprints (e.g. browser history and user-generated contents on social network sites), making unstructured data become constructed, which has become an unprecedented tool to understanding human behavior (Manyika et al., 2011). How can one's digital records be associated with one's personality and eventually test personality theory? Techniques powered by computer science and data science are employed to extract participants' information from their SNS. Combining both data from digital records and data from personality measures, researchers can create their own algorithms to access other datasets and predict participants' scores of personality measures in order to test hypotheses based on a personality theory. For instance, myPersonality project is one of the most successful attempts to combine big data and SNS with internet research in personality (Kosinski, Matz, Gosling, Popov, & Stillwell, 2015). According to Kosinski et al., more than 40 peer-review academic articles have been published based on myPersonality-gained data. myPersonality application provides Facebook users a way to understand their own personality through widely used personality tests (e.g. the Big Five), with instant feedback to users.

In Researchers recruit participants from the large and diverse pool available both online and offline. Facebook speeds up the process of data collection by collecting pre-existing information of participants (e.g. demographic profiles and social interactions). With participants' consent, these data can be recorded retrospectively in a convenient, accurate, and inexpensive way directly through Facebook without self-reports (Kosinski et al., 2015). Researchers are able to access users' social media networks using Application Programming Interface (API), which is a protocol used to collect data or set up experiments. Thus, researchers can examine users' information, including but not limited to demographic profile (e.g. gender,

nationality, working status, physical locations, romantic interests, and education history), user-generated content (e.g. self-portraits, photos, status, and comments), social network structure and relationships (e.g. family connection, friends), and activities (e.g. likes, share). For example, Park et al. (2015) conducted a study that provided evidence that written language from Facebook users is a valid way to assess personality.

By linking the Facebook Graph API to their own online survey or online behavioral experiments, researchers can collect both user-generated online information and new psychological data (i.e. results from psychological inventories and experiments). Furthermore, other social networking sites also could be applied to collect user-related data with respective API (e.g. Twitter API and LinkedIn API). In this way, user-generated online information can be quantified and analyzed along with psychological data by natural language processing software.

Mobile Internet

Researchers have begun to use mobile internet and smart electronic device (e.g. smartphones, smart band, and wearable computers) to conduct personality research. For example, de Montjoye, Quoidbach, Robic, and Pentland (2013) applied five psychological informative indicators, including basic phone use (e.g. number of interaction text), active user behaviors (e.g. response rate and latency for call), spatial behavior (e.g. distance traveled and number of places where calls were made), regularity (e.g. inter-time of call and text), and diversity (e.g. number of contacts), in order to predict participants' scores on the Big Five personality inventory using SVM algorithm. In addition, Sano et al. (2015) used scores from Big Five and other data collected from wearable devices (e.g. skin conductance, walk and run activities) and mobile phones (number of calls, online duration) to predict academic performance (GPA), perceived stress, quality of sleep, and mental health. They found that data collected from wearable devices had similar predictive validity to personality assessment. These devices provide alternative ways to self-reported assessment. In fact, Staiano, Lepri, Aharony, Pianesi, Sebe, and Pentland (2012) found that the combination of mobile behavioral data and social network analysis (see section below) predicted personality better than self-reported data. Furthermore, a study conducted by Youyou, Kosinski, and Stillwell (2015) found that computer judgments based on digital footprints collected from Facebook yielded better predictions than close-others and acquaintance ratings.

Social Network Analysis (SNA)

SNA is a strategy to study social structure using graph theory from both computer science and mathematics (Otte & Rousseau, 2002). Burt, Kilduff, and Tasselli (2013) discussed SNA as a method to study how patterns of interpersonal relations are associated with diverse psychological topics. With large datasets available online and advanced methods of data analysis, SNA could bring further insights to personality science. Currently, there are only few studies that used SNA and data from the internet. For example, Na, Kosinski, and Stillwell (2015) recently used data from Facebook and found that users in collectivistic cultures had less ego-centric networks (i.e. individuals themselves are centered in their networks and connect people of their networks) compared with users in individualistic cultures.

Conclusion

The capability of data collection and data analysis through the internet has tremendously innovated some fields, such as physics and biology (Lazer et al., 2009). Now personality science benefits from the internet to collect big data from hard-to-reach samples that would be almost impossible a few decades ago, helping to generalize the findings. Smartphones and other wearable computers are now being used to derive automatic determination of personality structure, which is a new and exciting way to assess personality.

Linguistic Analysis in Personality Research (including the Linguistic Inquiry and Word Count)

Margaret L. Kerr[1] and Jessica L. Borelli[2]

[1] *University of Wisconsin–Madison*
[2] *University of California, Irvine*

Our word choices communicate significantly more than we intend; in fact, researchers analyzing written and spoken language find that word use reveals a great deal about our thoughts, behaviors, and emotions. In an effort to understand the health benefits of expressive writing, a group of researchers developed a computer program known as Linguistic Inquiry and Word Count (LIWC; Pennebaker, Francis, & Booth, 2001) that analyzes the content and style of spoken and written language. Since its initial development 15 years ago, LIWC has become one of the most widely used applications for analyzing linguistic data. Using a computer program to analyze text reduces the resources required for research involving behavioral analysis, enabling investigators to systematically analyze massive quantities of data in very limited amounts of time.

How LIWC Works

The foundation of LIWC is a dictionary composed of approximately 4,500 words and word-stems. Within that dictionary, there are approximately 80 sub-dictionaries that represent word categories. The output contains a score for each category that represents the proportion of words that fall into that category (i.e. positive emotion words, pronouns) compared to the total number of words in the passage. The dictionaries are arranged hierarchically, such that one word can fall in to multiple categories. For example, the word "worry" falls into three word categories: anxiety, negative emotions, and affective processes. LIWC is designed to analyze both spoken and written language and has categories specifically targeted toward spoken language, such as fillers (i.e. "you know"), non-fluencies (i.e. "errr," "um") and swear words.

   The 80 word categories represent four main language dimensions. *Language composition* includes descriptive information such as total word count, average words per sentence, and percentage of words longer than six letters, as well as style words such as prepositions,

articles, and pronouns. *Psychological processes* include word categories aimed at tapping emotional, cognitive, and social processes and are similar to the categories seen in many other linguistic analysis programs. *Relativity* dimensions encompass time, space, and motion categories. Finally, *current concern* dimensions are common in content analysis and include categories such as money, occupation, and physical states.

The LIWC program underwent rigorous evaluation in order to establish a reliable and valid system for analyzing language. During the development phase, a panel of three judges made independent decisions about the inclusion of each individual word based on lists of potential words created by research assistants. The dictionaries were then re-assessed by a panel of three more judges, resulting in rater agreements ranging from 93% to 100%. In 2007, after over 100 million words were analyzed using the LIWC program it underwent a major revision of its dictionaries, which included expanding commonly used categories and removing some categories that had consistently low base rates or poor reliability (Tausczik & Pennebaker, 2010; Pennebaker et al., 2007). Since its initial development, LIWC has demonstrated strong reliability and validity across multiple studies (Mehl & Pennebaker, 2003).

LIWC researchers distinguish between two broad categories of words that are captured by text analysis. Content words are typically nouns, verbs, and adjectives that convey the substantive content of the text. Style words, also known as function words, are composed of articles, pronouns, prepositions, and auxiliary verbs (e.g. "it," "we," "was") that constitute the way we communicate information through language. Only about .05% of words in the English language are style words, yet we cannot communicate without them. These words make up about 55% of our spoken and written language. Although these words may appear less interesting, they actually reflect subtle but important differences in the speaker's and listener's shared knowledge, context, and relationships. Style words have been linked to personality, stress, depression, social status, and even physiological reactivity (Chung & Pennebaker, 2007). Because these words are so commonly utilized but their production and processing are largely unconscious, they offer a unique and implicit angle from which to examine our thoughts and behavior.

Applications of LIWC

Empirical work using linguistic analysis is expansive and covers a wide array of psychological constructs; a few of the major topics will be reviewed below. Language style matching (LSM) refers to the extent to which individuals mirror each other's word use and language style. Language matching occurs in all types of verbal interchanges between two or more people and is typically undetectable by both the speakers and outside observers. In fact, LSM levels are unrelated to self-reported quality of the conversation (Niederhoffer & Pennebaker, 2002). LSM is focused on the use of function words because these words are used frequently, processed quickly, and require shared social knowledge between conversation partners. LSM is thought to capture the extent to which individuals attempt to engage the other person as well as the degree to which those efforts are reciprocated. Higher LSM has been found to predict group cohesiveness and peaceful conflict resolution as well as romantic interest and relationship stability (Gonzales, Hancock, & Pennebaker, 2010; Ireland et al., 2011).

Verbal immediacy, a construct that represents degree of psychological engagement, is marked by high rates of first-person singular pronoun use and less frequent use of articles, long words, and discrepancy words. People using high verbal immediacy appear emotionally immersed in the topic being discussed while less verbal immediacy indicates a more distant or unengaged tone. For example, a statement such as, "I am mad about that" would score high on verbal immediacy whereas "That conversation angered me to the depths of my being" displays low verbal immediacy. Researchers have examined verbal immediacy as a predictor of formality, coping with trauma or loss and attachment security (Borelli et al., 2013; Cohn et al., 2004).

LIWC is commonly employed as a measure of verbal expression of emotional experiences. Validity studies reveal that more positive emotion words are used when writing about amusing events compared to sad or neutral events, and more negative emotion words are used when writing about sad events (Kahn et al., 2007). Emotion word use also signifies level of immersion in emotional experiences; those who use more negative emotion words when writing about trauma experiences also felt more physical pain (Holmes et al., 2007). In studies on savoring, participants who were instructed to write about positive relational memories used more positive emotion words than those asked to discuss a neutral event (i.e. morning routine; Burkhart et al., 2015).

Research Using LIWC

Age differences in language use have been found across longitudinal and cross-sectional studies. The use of first-person pronouns decreases over time while insight words, future tense verbs, and exclusion word use increase with age (Pennebaker & Stone, 2003). Other studies have found that younger people use more filler words (i.e. "you know") than older people (Laserna et al., 2014). An analysis of 14,000 text samples from 70 different studies revealed multiple gender differences in language use. Men use more complex language, such as longer words, more numbers, and more articles and prepositions, while women use more pronouns and social words, as well as less swear words than men (Newman et al., 2008).

Several studies examining thousands of text samples have found consistent patterns of word use across Big Five personality dimensions. Higher word count, fewer large words, and less verbal complexity has been associated with extraversion. People high in extraversion also tend to use more positive emotion words, less negative emotion words, and more social words. Conscientiousness and Agreeableness are consistently related to more positive emotion words, fewer negative emotion words, and fewer swear words, while Neuroticism is related to less positive emotion word use and more negative emotion words. Verbal immediacy is positively related to Openness to Experience and inversely related to Agreeableness (Mehl, Gosling, & Pennebaker, 2006; Pennebaker & King, 1999; Yarkoni, 2010).

The utility of LIWC has allowed researchers to examine other psychological processes that are difficult to detect via self-report. In studies on deception, Newman and colleagues (2003) concluded that when discussing the same topic, people instructed to tell a lie used fewer markers of cognitive complexity, more negative emotion words, fewer first-person pronouns, and fewer qualifiers (e.g. "but") than those telling the truth. In the context of groups and social relationships, first-person plural pronoun use has been linked to

higher social status and more group cohesion while first-person singular pronouns indicate lower social status (Kacewicz et al., 2014).

Assessing word use among depressed people and victims of suicide has illuminated the inner thoughts of those suffering from mental disorders. One study found that depressed students use more first-person pronouns and negative emotion words than students who have never been depressed (Rude et al., 2004). An examination of 300 poems from suicidal and non-suicidal poets revealed that suicidal poets used more first-person pronouns and more death-related words than non-suicidal poets (Stirman & Pennebaker, 2001). In a study of 40 suicide notes, researchers found that notes from completed suicides included more future tense verbs, more social references, and more positive emotion words than notes from attempted suicides (Handelman & Lester, 2007).

Word use has also been studied in the context of romantic relationships. In addition to the LSM research discussed above, women's use of first-person pronouns in instant message conversations predicts higher relationship quality among dating couples (Slatcher, Vazire, & Pennebaker, 2008). Alternatively, "you talk," or second-person pronoun use predicts lower relationship quality and more negative relationship interactions, while "we talk" is associated with more positive problem solving (Simmons, Gordon, & Chambless, 2005). "We talk" in couples is also predictive of better health outcomes in heart failure patients, and even more than self-reported marital quality (Rohrbaugh et al., 2008).

Conclusion

This brief review of a large and robust body of research reveals the importance of studying word use and its implications for understanding our personalities, relationships, and psychological processes. While we are beginning to gain an understanding of the dynamics of our language use, there is still a great deal left to discover. The development of Linguistic Analysis and Word Count has opened the doors to a greater understanding of human behavior through the way we speak, write, and converse.

Personal Narratives

Constance A. Sztukowski-Crowley[1] and Dallas R. Funk[2]

[1] *Port St. Lucie*
[2] *Indianola, Ia*

Brief Overview

Narrative inquiry is a relatively new qualitative methodology that investigates experience as told through the telling, retelling, and interpretation of personally meaningful stories. It is grounded in firsthand experience and is based on the idea that it is humanity's ability to use narrative to create meaning out of confusion by joining observation and theory in meaningful ways. The process moves from the researcher asking participants to tell their stories, to field texts, to interim and final research texts. Narrative inquiry draws from qualitative methods in ethnography, anthropology, history, and literature. It is not restricted to psychology, but can, instead, be found in many fields: social sciences, health, sexualities, law, human development, nursing, and literary theory (to name a few). Narrative inquiry is not so much a method with a specific set of techniques as it is a way of thinking, with narrativists understanding that "a person's lived and told stories are who they are and who they are becoming and that these stories sustain them." It is a fluid, reflexive process with interpretations and adjustments to understanding repeatedly evolving as the inquiry – the narrative – continues to be lived out.

The Evolution of Narrative Inquiry

Some of the earliest work with personal narratives was done by Freud, Allport, Piaget, and Erickson. The Russian philosopher Mikhail Bakhtin and the French philosopher Paul Ricoeur are also important. Other narrativists, depending on their area of emphasis, will look to researchers such as: Wilhelm Dilthey, Edmund Husserl, and Martin Heidegger, as well as Carol Gilligan and even anthropologist Clifford Geertz.

Ted Sarbin edited *Narrative Psychology: The Storied Nature of Human Conduct* in 1986 and argued that psychology was in need of a transformation to the more organic idea of

narrative. This book contained chapters by a variety of psychologists who were developing methods for incorporating and investigating the ways people and narratives interact. Sarbin came to believe that when we share our own narratives, for whatever purpose, we are doing more than cataloging events; we are weaving the story of our lives.

Jerome Bruner, an early pioneer in the field, began to explore narrative as applied to psychology in the 1990s. He believed narrative was an organizational tool and used it to study how people create meaning and construct their reality. People are predisposed to organizing experiences in a narrative manner, with cultures creating the boundaries of what are acceptable stories and a narrative lens through which experiences become understandable to both the self and the community.

Polkinghorne, developing along the same lines as Sarbin and Bruner, emphasized the dynamic aspect of narrative: the idea that we are in the middle of our lives – our plots – and must revise our story constantly. Our identities and self-concept are expressions of a developing story, with no real idea of how they will end. As we engage in this revision and development, we reorder our memories to fit an organization that makes sense according to our newest experiences.

Terms and Definitions

Personal narratives allow the researcher to understand and inquire into an individual's lived experience through the relationship between researcher and participants which takes place over time. Although narrative inquiry shares features with other forms of qualitative inquiry, personal narrative research is a distinct methodology. Connelly and Clandinin (1990) identified three such "commonplaces" to identify those qualities that make personal narrative research distinct: temporality, sociality, and place. These commonplaces are used to guide the researcher, providing framework and dimensions for the narrative inquiry. While other qualitative methods may at one time or another touch upon or focus on these commonplaces, it is the unique characteristic of personal narrative research that incorporates a simultaneous examination of all three commonplaces.

Temporality

Temporality refers to the timing of the story being told. It is vital to be aware that people's lives – their narrative story – always have a past, present, and future. The places, people, and stories they tell all occur in process. Narrativists needs to keep in mind the temporality of participants' – and their own – lives, as well as that of places, things, and events. None of it is a static point in time, but is constantly evolving and changing. This occurs as the future transitions to the present, the present to the past, and the views of each change to incorporate knowledge gained in the process.

Sociality

The second commonplace, sociality, refers to two distinct characteristics: the personal conditions and the social conditions of their participants. Personal conditions refer to the

feelings, hopes, and desires of both the inquirer and the participant. Social conditions include the environment, the surrounding people, and the cultural factors and forces in the participant's and researchers lives. It is important to note that, in both instances, the researcher's conditions are a vital part of the research and cannot be excluded from the relationship inherent to the inquiry.

Place

Place can be either a single place or a series of places; both of the narrative being told and of the location in which the narrative is being told. Place is a particular position or point in space and includes concrete, specific boundaries. Just as narrativists must keep in mind temporality and sociality, inquirers cannot ignore the commonality of place in their chosen research. All events take place somewhere, in some place, and this cannot be removed from the stories we are telling.

Narrative Inquiry Research Design

Narrative inquiry research does not just happen. It requires thought and planning; it must be designed. This includes evaluating the justification for the research, naming the phenomenon – the what – that is being researched, where to start the narrative inquiry and what methods to use, and, finally, interpreting and analyzing the data.

There are three different ways to justify narrative inquiry research: personal, practical, and social. The justification tells the researcher – and the scientific community as a whole – why the research is important. While personal justification is rarely described in great detail in published narrative inquiries, it is important nonetheless. It allows the researcher to think about their own life in relation to the study.

Beyond that, however, and keeping the research question in mind, a narrative inquirer must think narratively – using the three commonalities – about the phenomenon throughout the research. Ideally one frames a research question without a precise definition, looking instead to frame the research in a flexible manner that contains a heavy degree of searching and reformation.

As with other forms of qualitative research, a prepared researcher will determine and describe the field texts (a narrative inquirer's data) that will be collected and compiled. These texts, or data points, can include transcripts of conversations, field notes, family stories, artifacts, photographs and other accounts that are composed by narrative inquirers and participants to represent aspects of the participants' lived experience. Ideally, the research collects a variety of texts and stories in order to triangulate the data. This helps improve reliability and validity.

These elements must be combined with a willingness to think creatively and challenge the notion that the phenomenon is fixed and unchanging. Narrative inquiry always takes place in the middle of changing and evolving experiences. Both the inquirer and the participant continue to learn and grow as the narrative inquiry takes place. The phenomenon, and the approach to studying the phenomenon, must learn and grow just as the people involved do.

Interpreting and Analyzing the Data

The fluidity of a narrative inquiry results in an equally fluid process of data analysis and interpretation. The successful narrativist will move from the field and field texts, to interim research texts, to final research texts, adjusting the research protocol and returning to earlier stages as needed, based on new insights gleaned throughout the process. While in the field, a narrativist will find themselves in the middle of stories that are being lived and shared simultaneously. Interpretation is naturally an ongoing process and requires that researcher and participants acknowledge that their past is always colored and altered by the lens of their present. When moving from the field and field texts to interim research texts it is common to want to move on to objective analysis. However, to increase both validity and reliability, the researcher must engage in a cyclical process of field research and later analysis until only repeated themes are found in the stories – until the data has reached a saturation point. In addition, narrative inquirers may want to place space between themselves and their participants. It is important to resist that impulse. A narrative must include the three commonalities, from both the inquirer's and the participant's point of view, in order to be a narrative.

Most narrative research tends to include far more data than what ends up in the final text. It is also important when developing these final research texts that the researcher is transparent in sharing the process for choosing what to include and that the final voice that comes through is that of the participants, not the inquirer.

Challenges

As with other types of research, narrative inquiry is not composed solely of strengths. The following challenges are an inherent part of narrative research: positioning in the scientific community, ethical considerations, and representing the appropriate voice.

When considering a particular phenomenon, researchers tend to arrange research and compile data in relation to the scientific community as a whole. Narrative inquiry, however, tends toward having a sense of incompleteness – due to the fact that it takes place in the middle of participants' lives – and rarely leads to the generalizations or certainties that are expected in other forms of research. Knowledge of a variety of epistemological and ontological assumptions is an important component of narrativists' ability to find the borders around the relationship between researcher and participant, experience and content, and the understanding of how experience is lived and shared with a broader audience. When this happens, narrative inquiry can lead toward "wondering about and imagining alternative possibilities" (Clandinin & Huber, 2014).

Ethical considerations are an especially important element of narrative inquiry. Not only must a narrativist hold themselves to the ethical standards of typical research, but (s)he must also remember that the close relational aspects of narrative inquiry require a heightened commitment to the idea of "do no harm." Striving to understand before being understood, suspension of judgment and disbelief, and a commitment to the idea that relational responsibilities are longterm are important steps in meeting the ethical needs of a narrative inquiry. Additionally, there is a final responsibility to develop the voice and signature of the research texts with care.

With all of the choices for field texts and narrative forms, as well as the wide variety of backgrounds that can be encountered both through the inquirer and the participant(s) – as well as the final audience, the researcher will be required to balance many different elements. The most important element, however, is the voice of the participant, the one (or ones) whose story is being told. Receiving feedback throughout the process from a variety of people, with a variety of backgrounds, can help the narrativist strike the right chord. When done correctly, narrative inquiry is about life stories, connecting story and life as we simultaneously live and create our stories.

Personality Development Across the Lifespan

Vitoria Meira[1] and Jessica L. Borelli[2]

[1] *Claremont Graduate University*
[2] *University of California, Irvine*

The term "personality" refers to differences between individuals in cognition, emotion, and behavior, and how these parts function together. Although there are no typological models for personality, there is growing evidence suggesting that broad individual differences in personality can be categorized. The Five Factor Model organizes these broad, higher-order traits, into five domains: Extraversion, Agreeableness, Consciousness, Emotional Stability, and Openness to Experience.

In the past decade, research has shown that personality traits are neither solely biologically-based and stable, nor fluid and prone to change. Instead, with age they develop through continuous and discontinuous processes. Patterns of discontinuity are easily identified in childhood considering children's rapid physical and psychological development. Longitudinal studies document links between early childhood temperament and the Big Five personality traits in adolescence and adulthood. Temperament, also referred to as lower-order traits, consists of narrow traits including components of self-regulation and emotionality. Support for typological models of temperament are based on several caregiver temperament questionnaires for children which have yielded consistent types of temperament. Current models suggest that temperament consists of the following traits: positive emotions or pleasure; fear or inhibition; irritability, anger, or frustration; attention; activity level; and soothability or adaptability.

Temperament and personality trait research have shown that variations in behavior (i.e. talkativeness) can be understood by observing the influence of higher-order traits (i.e. extraversion) on variations of lower-order traits (i.e. sociability). The overlap between childhood temperament and personality traits in adulthood may be explained by several factors. Recent empirical work has demonstrated that temperament and personality are both moderately hereditary, molded by experience, and influenced by specific habitual positive and negative emotions.

Assessment of Personality Across the Lifespan

Personality assessments vary in the extent to which they focus on single versus multiple constructs, are designed for children or adults, and index variations in non-pathological or pathological personality traits. Types of assessments include: self-reports and questionnaires, informant reports, life data (verifiable police or medical records, web pages), behavioral observation data (temperament and physiological measures), and projective tests (interpretations of ambiguous ink blots, pictures, or drawings). The assessments discussed below measure the stability and change of non-pathological personality development throughout the lifespan.

Contemporary Child and Adolescent Personality Assessments

A commonly used temperament assessment for older children is the Junior Temperament and Character Inventory (JTCI) based on Cloninger's psychobiological model of personality. The JTCI is a self-report administered to children between six and 14 years old and consists of four temperament traits (novelty seeking, harm avoidance, reward dependence, persistence) and three character dimensions (self-directedness, co-operativeness, and self-transcendence).

In addition to self-reports and parent reports, temperament may also be assessed with neurological and physiological measures. Contemporary personality researcher Jerome Kagan has shown that infant reactivity levels are highly genetic and linked to adult inhibition levels by using measures observing heart rate, hydrocortisol levels, and amygdala activation.

Furthermore, research suggests links between early temperament and later personality traits. Specifically, parent and teacher reports, behavioral tasks, observational measures, adjective lists, and the California Child Q-set have produced factors similar to the Big Five in studies of three-year-old children to adolescence. Studies using the NEO Personality Inventory-3 (NEO-PI-3) have shown high test-retest correlations. The NEO-PI-3 measures the Big Five domains of personality and the six facets defining each domain. It may be administered to children as young as 12 years of age.

A study by Kagan examining the link between early childhood temperament and the Big Five measured behavioral styles of 1,000 three-year old children and their self-reports on the Multidimensional Personality Questionnaire (MPQ-BF) at age 18. The MPQ-BF consists of 155 items measuring four types of non-pathological broad traits (Positive Emotional Temperament, Negative Emotional Temperament, Constraint and Absorption) and 11 primary trait dimensions (well-being, social potency, achievement, social closeness, stress reaction, alienation, aggression, control versus impulsivity, harm avoidance versus danger seeking, traditionalism, and absorption). The study found that three-year-olds characterized as *undercontrolled* (impulsive, restless, and distractible) became 18-year-olds with low *constraint* and high *negative emotionality*. *Inhibited* three-year-olds (fearful and easily upset by strangers) became 18-year-olds with high *constraint* and low *positive emotionality*. Similarly, children at age three who were either *well-adjusted*, c*onfident*, or *reserved*, all

scored consistently with their qualities at age 18. Thus, early childhood temperament is predictive of adolescent traits and temperament is stable over time.

Contemporary Adult Personality Assessments

Although controversy surrounds the increased reliance on the Five Factor Model, factor analyses of adjective lists from countries such as the USA, Germany, Poland, Japan, and the Netherlands support the Big Five. A commonly used self-report or informant-report assessing the Big Five is the Revised NEO Personality Inventory (NEO-PI). The NEO-PI assesses emotional, interpersonal, experiential, attitudinal, and motivational styles by measuring the five domains as well as the six facets defining each domain. Another questionnaire assessing the Big Five is the Sixteen Personality Factor Fifth Edition Questionnaire (16PF), which has high concordance with the NEO-PI. The 16PF contains 185 multiple-choice items predicting several behaviors such as leadership style, compatible occupations, self-esteem, coping patterns, empathy, conscientiousness, social skills, and power dynamics.

Data support the stability of personality traits indexed using assessments grounded in the Five Factor Model – a meta-analysis of personality stability revealed moderate test-retest reliability; moderate interrater reliability; increases in stability with increasing age; decreases in stability with increasing time intervals between observations; and consistency in reliability across the Big Five traits, assessment method (i.e. self-reports, observer ratings, and projective tests), and gender.

The current studies documenting personality stability and change consider distinct types of stability. The continuity of the exact same thoughts, feelings, and behaviors across time, referred to as homotypic stability, includes four types. "Absolute stability" results from maturational processes or social-contextual factors which generally influence a population, and can be examined longitudinally by measuring individuals in phases of transition. Studies document coherent patterns of mean-level change into middle age in cross-sectional and longitudinal studies. In a cross-sectional study by Srivasta, John, Gosling, and Potter (2003), 132,515 adults aged 21–60 completed the Big Five Inventory online. The BFI consists of 44 items rated on a 5-point Likert-scale. The study showed that the social dominance facet of extraversion tends to increase to the mid-30s and then plateau, whereas the social vitality facet tends to peak, remain stable across mid-life, and decline after age 55. Average levels of *agreeableness* tend to increase gradually across the lifespan. Average levels of *conscientiousness* also gradually increase, but may decline in mid-life or old age. Average levels of *neuroticism* gradually decline across the lifespan, but may increase in old age. Finally, *openness to experience* tends to increase during adolescence and gradually decrease across the lifespan.

The patterns of absolute change can be explained in two different ways. From an *intrinsic maturational position*, changes in personality may be biological influenced. Studies show that all Big Five traits are genetically influenced similarly in both men and women, and that these factors affect the preservation of individual differences over the lifespan from adolescence onward. This is consistent with Allport's (1973) proposition that personality traits are "neuropsychic entities." In fact, current evidence suggests that the Big Five have neurobiological correlates. *Extraversion* is associated with biological systems of motivation and approach behaviors. Systems of behavioral control, anxiety, and threat detection are related to *neuroticism*. *Agreeableness* is linked to systems involved in social connection and

affection. Finally, the executive control systems involving the prefrontal cortex are related to *conscientiousness*. According to the *life course position*, however, changes in personality are due to the interaction of an individual's social roles and life experiences. Existing evidence supports the *life course position,* although some changes in personality are biologically influenced.

The second type of stability is "differential stability" – the degree to which traits are ordered and consistent over time compared to an individual's relative placement in a group. Evidence using self-reports and informant reports of rank-order stability show that average levels of all Big Five traits increase across the lifespan due to the decrease of maturational changes. Differential stability is remarkably high. The only construct more consistent than personality traits is cognitive ability. In a recent review of 80 longitudinal studies synthesized according to the Five Factor Model, Roberts and DelVecchio showed that with an interval of seven years, test-retest correlations increased from childhood to early adulthood and kept increasing until a plateau between 50 and 70 years of age.

The third type of homotypic stability is "structural stability" – the similarity over time in the patterns of covariation of traits on personality scales. Structural change may indicate a developmental transformation. For example, factor analyses of cognitive test items in early childhood suggest that there are qualitative changes intelligence. Conversely, most studies of personality have shown that there do not appear to be qualitative structural shifts beyond adolescence in personality traits.

Absolute, differential, and structural stability focus on the stability of samples of individuals. Finally, "ipsative stability" is the continuity of personality traits and how they are preserved over time at the individual level. Little longitudinal research has been conducted from this point of view. A major study employed the Q-sort technique by computing correlations across the set of attributes' Q-correlations between an individual's Q-sort profiles at different time periods. Results showed higher Q-correlations between early and late adolescence, than between adolescence and adulthood. However, intra-individual correlations were moderately negative, to zero.

In contrast to homotypic stability, heterotypic stability describes personality coherence – the continuity of inferred genotypes' attributes presumed to underlie different phenotypic behaviors. It can only be understood by referencing the same trait according to a theoretical conceptualization of it. For example, the capacity to delay gratification during toddlerhood is consistent across development as it predicts adolescents' academic and social competence 10 years later.

The different types of stability and change are influenced by multiple factors including self-reflection and how much positive or negative reinforcement individuals receive regarding their behaviors. However, it is unclear whether environmental stability is the product or cause of personality continuity. Stability may be promoted as individuals' expectations generate self-fulfilling prophecies or as they immerse themselves in environments that fit their individual characteristics. Reactive person-environment transactions are characterized by individuals who interact with the environment subjectively. In evocative person-environment transactions, individuals evoke reactions from others based on their unique personality characteristics. The person acts, the environment reacts, and the person reacts back. In proactive person-environment transactions, individuals' personalities affect their social relationships which serve to distinguish differences between people.

Conclusion

The Five Factor Model offers a compelling delineation of associations between child temperament and adult personality. However, the lower-order facets of the NEO-PI-R have been criticized for lacking empirical validity. Future studies should employ new empirical strategies assessing facets to complement the assessment's strength in discriminant validity, heritability, and developmental progress.

Research in personality development shows that patterns of stability and change of the Big Five are complex and influenced by person-environment transactions. A plethora of personality assessments exists; however most are self-reported scales, which may lead to faked good or bad responses. Thus, increased empirical analysis of items prior to their inclusion in personality measures is highly recommended.

In considering the limitations of the field of personality psychology, it is important to note that the field has expanded over the past decade and advances in methodology will continue to add to the knowledge of the origins of individual differences.

Personality in Non-Humans

Amber de Vere and Lucas A. Keefer

University of Southern Mississippi

That there are differences in behavior between individuals may seem obvious. Indeed, these differences have been a subject of interest for thousands of years (e.g. Hippocrates, Plato; 370 B.C.). More modern research has examined these differences in increasingly fine detail, leading to the formation of personality psychology. Until recently, this systematic study of individual differences focused on those of humans. However, the field of non-human animal personality has exploded in the last few decades, with empirical data now available for more than 65 species (Gosling, 2001). Across human and non-human literatures, personality is defined as individual differences in behavior that are consistent across time and contexts (Gosling & John, 1999). There has been increasing recognition that regardless of species, there are a large number of components to these individual differences, including underlying genetic, neurological, cognitive, and motivational elements (Uher, 2008). In order to examine these differences in non-human animals, methods for assessing human personality, as well as existing ethological methods, have been adapted for this area of psychology.

Behavioral Coding

Two methods have become particularly dominant in non-human personality data collection: behavioral coding and trait rating. The former has a long history in other areas of animal research, with roots in the traditional study of behavior (Tinbergen, 1951). In its simplest form, this method involves observing an animal and recording the frequency and/or duration of behaviors of interest. Which behaviors these are depends both on the study's aims as well as the subject species. For example, a personality assessment aiming to reveal general personality dimensions in an unstudied species may measure the frequency of all behaviors known to occur in that species, as researchers would have no previous basis on which to discriminate. In contrast, an assessment measuring a single trait, such as curiosity, in a well-studied species would likely be

able to measure a small number of relevant behaviors elucidated from previous literature (e.g. gaze duration, approach latency).

Once the behaviors of interest have been identified, the method, duration, and frequency of observations must be determined. As observations made at a single time point are not reliably predictive of overall behavioral tendencies, data from multiple observations are typically aggregated to achieve high reliability and validity (Uher, 2008). In practice, this means that each animal must be observed more than once, although there is no universally agreed minimum number of observations. Within each observation, one further major decision concerns the type of sampling method, and two approaches are common. In focal follow designs, each animal is exclusively observed for a period of time, while scan sampling involves recording the behavior of every animal in a group at pre-determined time intervals (Altmann, 1974).

Within this basic observational methodology, there are two major variations; observations may be made in either a naturalistic setting, without any human manipulation or intervention, or in an experimental environment in which animals are exposed to standardized stimuli (Diederich & Giffroy, 2006). The former is particularly useful for animals which are difficult to test in controlled circumstances, such as large, mobile, and/or rare species. As the potential stimuli to which animals respond in an unmanipulated environment are not standardized, many more repeated observations are required in order to build a representative picture of each individual's tendencies. For example, in an assessment of African elephants, each animal was observed 160 times over two summers, for a total of 40 hours each (Horback, Miller, & Kuczaj, 2013).

The second type of behavioral coding, experimental testing, allows for greater standardization and control of possible confounds. As a result, individual animals can be statistically compared across very specific conditions and behaviors. This specificity and standardization means that unlike naturalistic coding, extensive repeated observations are not required. Instead, a variety of individual tests may be carried out and these may each target the same or different personality traits. As a result, behavioral tests are more efficient than naturalistic coding. In some species, such as the domestic dog, this type of testing is by far the most common method for assessing individual differences (Diederich & Giffroy, 2006; Jones & Gosling, 2005).

Historically, many have regarded behavioral coding as the gold standard for independent, objective assessments of animal personality. However, both experimental and naturalistic coding involve inherently subjective judgments (Uher, 2008). The selection of relevant behaviors is based on previous literature and knowledge of the range of behaviors performed by a species, which is often incomplete for many species. Furthermore, the behavioral categories and definitions used in personality assessments are always from a human perspective. This necessitates subjective judgments, such as the interpretation of the appearance of a behavior, or its function. For example, bottlenose dolphins frequently exhibit an open mouth behavior in aggressive contexts (Overstrom, 1983). Even though this behavior is based on a physical classification (mouth open or closed), there are still several subjective judgments that must be made to record the presence or absence of this behavior: How open must the mouth be to be classified as "open mouth" behavior? If the behavior is observed while a dolphin is engaged in an affiliative, social interaction, should it still be classified as aggressive? Such subjectivity in even the simplest of behavioral definitions

clearly demonstrates that while behavioral coding is an extremely useful method, it is not infallibly objective. Furthermore, even if we were able to standardize behavioral definitions and interpretations across observers, different species manifest similar personality traits in the form of drastically different behaviors, and even within-species variation between individual externalizations of the same traits. For instance, it is unlikely that a curious human exhibits the same behaviors exhibited by a curious bottlenose dolphin, while one fearful dolphin may display a flee response in a context in which another displays aggressive behaviors.

Trait Rating

The major methodological alternative to behavioral coding is trait rating, which has its roots in human personality research. In that context, friends or family members rate a focal individual on trait descriptors. For non-humans, human judges rate individual animals on specific personality traits, and such ratings have proven reliable and valid across species and traits (Uher, 2008). In a basic trait rating design, traits are assembled into a questionnaire which asks the rater to place a subject animal on a scale for each trait. Raters may complete multiple questionnaires, each for a different animal, and questionnaires can be anywhere from just a few items long up to a few dozen. Within this basic paradigm, there are two major ways in which methodology varies across studies: rater identities, and the pool of trait items on which animals are rated.

Raters are typically individuals who have extensive experience with the subject animals, such as zoo keepers (e.g. Horback, Miller, & Kuczaj, 2013) or pet owners (e.g. dogs; Jones & Gosling, 2005). This ensures that raters have had sufficient repeated encounters with the subjects, and can therefore aggregate this experience into valid ratings. However, there is no consensus on the expertise or familiarity required in order for someone to act as a rater, although more experience is generally considered to be better. However, even when all raters have long-term experience with the subjects, the nature of their experience seems to play a role in their interpretation of an animal's personality. For example, veterinarians and animal care staff did not produce reliable ratings of Garnett's bushbabies, likely due to their dramatically different experiences with the subjects (Highfill, Hanbury, Kristiansen, Kuczaj, & Watson, 2010). Finally, there is evidence that untrained, inexperienced raters are able to produce reliable and valid ratings of certain traits, in both naturalistic and behavioral testing settings (e.g. Carlstead, Fraser, & Kleiman, 1999; Petelle & Blumstein, 2014). In reality, the challenges associated with achieving a reasonable sample size in non-human personality research mean that whichever raters are available will tend to be used, and any who deviate from the majority in reliability analyses can be excluded.

In order to generate a pool of traits on which subjects are to be rated, studies have predominantly used a top-down approach, in which items are sourced from an existing theoretical framework (Weiss & Adams, 2013). Typically, the existing model used is a human one (e.g. the Big Five), which facilitates cross-species comparisons at the cost of a potential anthopocentric bias. This bias is already somewhat intrinsic in the rating method, given that trait items are inherently human descriptors of externalized personality traits (Uher, 2008). Nevertheless, there are several methodological approaches that can be employed to

mitigate this limitation of trait rating. First, other trait selection strategies can be incorporated. For example, "experts" on a certain species, such as academics or wildlife staff, may be asked to nominate trait words which they feel are relevant to the focal species, or a species' behavioral repertoire could be examined to identify areas of variability and related traits (e.g. Freeman et al., 2013). Doing so may help to eliminate any blindspots caused by simply transferring a model of human personality to a non-human context.

Second, the definitions accompanying traits on a rating questionnaire can either be phrased in terms of species-specific behaviors or using typical dictionary definitions. The latter, trait-adjectives, facilitate cross-species comparisons, as these standardized definitions maintain uniformity across species. However, as these traits are defined in terms of their meaning for humans, they are likely to be interpreted by raters as such. This means that raters may ignore potentially important aspects of species-specific traits which may not be represented in the vocabulary of human languages (Uher, 2008). One alternative reduces this bias by adapting trait-adjectives to a focal species through definitions phrased in terms of species-specific behaviors (e.g. aggressive: frequently bites or hits other animals; Uher, 2008). In support of this behavior-descriptive approach, associations between behavior and ratings of behavior-descriptive terms are stronger than those between behavior and trait-adjectives.

Conclusions

The use of trait rating and behavioral coding has surged with increased acceptance of animal personality as a valid area of study. Clearly there are advantages and disadvantages to both major methods of data collection. Given these almost benefits and drawbacks for each method, a growing number of personality researchers advocate the use of multiple methodologies. It is expected that if different methods are measuring the same underlying personality constructs, results produced from each method should correspond to some extent (Weiss & Adams, 2013). For example, African elephants rated as highly Playful also tended to score highly on the behaviorally coded Playful trait (Horback et al., 2013), thus providing stronger evidence for an elephant Playful trait. Such multi-method approaches are therefore likely to provide the most comprehensive picture of animal personality, as well as help to improve our understanding of what is actually being measured by each method. Using methodological combinations alongside cross-species comparisons allows questions to be asked about not only the evolutionary origins of individual personality traits, but also their organization in broader frameworks of personality.

Physical and Virtual Spaces

Charity A. Smith and Ingrid K. Weigold

The University of Akron

Physical and virtual spaces research refers to the study of how individual differences manifest in both physical and virtual environments. Researchers theorize that individuals communicate core aspects of their personality, such as preferences, values, attitudes, and goals, through what they make present, either intentionally or as a result of their behaviors, in both the physical and online environments they create. Further, researchers posit that these manifestations are also communicated to others. There is evidence suggesting that observers form impressions of the individual's personality based upon the space they inhabit.

Historically, this work centered on the area of physical spaces and possessions, with a particular focus on individuals' bedrooms and offices. Theoretically, three mechanisms have been proposed to explain how individuals directly affect physical spaces (Graham, Sandy, & Gosling, 2011). These mechanisms – identity claims, thought and feeling regulators, and behavioral residue – have varied purposes and provide different information about the individual occupying a particular space.

Identity claims are direct and intentional statements intended to communicate key aspects of one's personality. Such claims most often utilize symbols, terminology, and themes that are common to the social vernacular and are thereby easily understood by the intended audience. The degree to which one communicates such messages, as well as the intentionality of the communication, varies. Further, the content expressed and message of delivery may change based upon the individual's intended audience. For example, one may choose to express different claims socially versus professionally (Graham et al., 2011).

Thought and feeling regulators refer to aspects of the environment that are manipulated by an individual to make the environment more conducive to certain activities or emotional states. Thought and feeling regulators can communicate messages regarding an individual's personality, although they are intended to serve the desires of the individual with respect to his or her cognitive and emotional needs (Graham et al., 2011).

Behavioral residue consists of changes in the environment that occur as the result of how people behave in or engage with that environment. It is what is "left behind" in a space

after a person has occupied it. A person's behavior, whether unique to the moment, habitual, or patterned, leaves evidence of the individual's action or inaction within a space (Graham et al., 2011).

Physical Spaces

Physical space may constitute a number of locations and is a construct broad in range and subjective in meaning. In order to operationalize a term more suited for research, Gosling and colleagues coined the phrase "personal living space" (PLS). PLS refers to an individual's space within a space, meaning any area which a person regularly inhabits and that is understood by others to be the assigned space of that individual. PLSs include a wide variety of spaces, such as a cubicle within an office, a dorm room, or a prison cell. Much of the research on PLSs relies on self-report and, in some cases, on photographs of the PLS of interest. Gosling, Craik, Martin, and Pryor (2005) developed the Personal Living Space Cue Inventory as an attempt to standardize the measurement of valid cues detected by PLS observers; however, this method proved both costly and time consuming.

Researchers studying manifestations of traits in physical spaces commonly assess individual differences using the Five Factor Model of personality (the Big Five), with all five traits being discernibly present in PLSs (see Graham et al., 2011, for a review). For example, studies indicate that those high in openness often display a wide range of interests within their space, particularly items such as books, magazines, photos, and souvenirs that denote diverse interests. Additionally, and consistent with behavioral residue research, those who are highly conscientious are more likely to have spaces that are well organized and clear of clutter (Gosling, Ko, Mannarelli, & Morris, 2002). When assessing one's PLS, there is also evidence to suggest that, with some accuracy, observers are able to form impressions of the owner of the space. This is particularly true when observers utilize valid cues to form the basis of their assessment on the traits of extraversion, openness, and conscientiousness (Gosling et al., 2002).

Unlike PLS, research on the communication of individual differences through one's possessions lacks cohesion with respect to both the definition and categorization of the individual's personal items, making research in this area markedly difficult. Although there does not appear to be a common definition to operationalize "possessions," the three most prominent types of belongings discussed in the literature are cars, consumer goods, and objects in which people place personal value. Such research also lacks a consistent means of categorizing possessions; however, past studies have done so by price, symbolic or sentimental value, and utility. Further, although there is often overlap in terms of identity claims, possession research also includes items found outside of one's PLS (see Graham et al., 2011, for a review).

Whereas PLS research commonly utilizes the Big Five to examine individual differences, possession researchers commonly focus on behaviors surrounding the purchase of items, patterns of consumption, and individuals' needs as motivators of consumer behaviors (see Graham et al., 2011, for a review). Early work in individual differences and possession research included the work of Allen L. Edwards, who developed the Edwards Personal Preference Schedule (EPPS) in 1959. Utilizing Henry Murray's theory of psychological

needs, the EPPS is commonly used to help determine the relation between individuals' needs and brand preferences. Other personality measures utilized in possession research include the Thurstone Temperament Schedule (1950), the Gordon Personality Profile (1953), and Jackson's Personality Research Form (1967). Findings indicate that those who are highly agentic endorse a desire for more instrumental possessions, whereas those who are more communal place more value on symbolic possessions. With respect to gender differences, there is some research to indicate that men value items that are instrumental, such as sporting goods and tools, whereas women place greater value in shared experiences or items that represent these experiences, such as coffee (see Graham et al., 2011, for a review).

Virtual Spaces

With the advent and pervasive reach of the Internet, PLS research has expanded to include the spaces individuals create and inhabit online. Online social networks (OSNs), massive multiplayer online role-playing games (MMORPGs), personal websites, electronic communication, and blogs now provide individuals with opportunities for self-expression through the use of written content, media and picture sharing, and virtual avatars, which are the subdomains of virtual space most commonly researched (e.g., Back et al., 2010; Gosling, Augustine, Vazire, Holtzman, & Gaddis, 2011; Vazire & Gosling, 2004).

As with research on physical spaces, the Big Five is the most common assessment tool to detect manifestations of individual differences in the virtual world, with at least some traits being found in each of the above subdomains. Consistent with PLS research, the Big Five has also been used to test the accuracy of observers' perceptions of users' personality traits when assessing content shared by others. Much of the current virtual space research focuses on Facebook. Research indicates that those high in openness and extraversion appear to "like" a broad range of interests, are involved in a number of and variety of "groups," and have a higher number of friends/followers than their introverted counterparts. Further, there is evidence to suggest that observers may be able to accurately perceive conscientiousness and agreeableness, simply by viewing the Facebook pages of those scoring high on these traits. Similar findings have been shown for personal web pages (e.g., Back et al., 2010; Gosling, Augustine, Vazire, Holtzman, & Gaddis, 2011; Vazire & Gosling, 2004).

Studies focusing on writing styles, affect, and word-use frequency show evidence of individual differences in blogs. In general, researchers have found that those high in neuroticism were more likely to make personal references and choose negative words with greater frequency; conversely, authors higher in agreeableness and extraversion were more likely to employ positive word choices and prosocial language. Self-selected email addresses also communicate individual differences. For example, people scoring low on agreeableness are more likely to have email addresses that are self-promoting (Graham, Sandy, & Gosling, 2015). Conversely, research conducted to determine if the same holds true for MMPORG screennames, particularly those of World of Warcraft users, indicates that a player's choice of screenname does not appear to relate to the Big Five personality traits (Graham & Gosling, 2012).

Limitations and Future Directions

With regard to physical and virtual space research, there is little continuity in how such spaces are defined, which measures of individual differences are used, or how data is gathered. As indicated earlier, the Big Five appears to be the most commonly used assessment tool in the PLS and virtual space literature; however, it is seldom used in research regarding possessions, which are, arguably, an important part of what comprises PLSs. The application of this method to possession research may allow for trends in individual differences, as expressed through possessions, to emerge. Conversely, research in this field would benefit from the use of additional measures beyond the Big Five in order to capture additional traits such as narcissism, self-efficacy, and shyness. Further, much of the current literature relies heavily on participant self-report, which may result in less reliable data. Developing additional means of data collection, particularly methods that can be standardized, may result in increased reliability, as well as an increased ability to generalize findings to larger populations (see Graham et al., 2011).

Among those who study virtual and physical spaces, there is a call for research regarding the home environment as a whole (Graham, Gosling, & Travis, 2015). Researchers argue that there is still much to be learned about both how PLS may differ across rooms and the ways in which individuals value and utilize their communal space as a whole. Principal investigators cite the need for further investigation of several areas of ambience that are both spatially influenced and that influence those within a given space. Such research would not only look at how individuals are impacted by their PLS and how messages are communicated to others through their PLS, but it would also examine the interplay of the PLS of all inhabitants within a home and how the ambient themes of each PLS serve to impact individuals.

Finally, an important future direction for PLS and virtual space research includes a look at cross-cultural individual differences (e.g., Gosling et al., 2005). Although there are some studies that discuss differences by gender, to date, researchers have paid little attention to differences between Eurocentric and other cultures, age groups, or individualistic and collectivist cultures.

Psychobiography and Case Study Methods

Constance A. Sztukowski-Crowley

Port St. Lucie, FL

Psychobiography

The aim of psychobiography is to understand individuals. Psychobiography is neither a case analysis, which focuses on pathology, nor is it biography, which focuses on the "what" of a person's life. Psychobiography applies psychology to single cases, to individual lives, to understand motives of behavior, the "why" of that person's life. Psychobiography is the explanation of a person's life story.

Classic Contributions to Psychobiography

Sigmund Freud is probably the first person to apply this approach when he wrote his analysis of Leonardo da Vinci in 1910 and then later his book *Moses and Monotheism* in 1939 (which was reprinted in 1964). During the early part of the twentieth century, psychoanalysts wrote many psychobiographies. Among these are analyses of Shakespeare as revealed through Hamlet, Richard Wagner, the artist Giovanni Segantini, Amenhotep IV, Martin Luther, and Socrates. Some of the other research on notable individuals would include Catherine Cox's study in 1926, supervised by Lewis Terman, to estimate *The Early Mental Traits of 300 Geniuses*. Among these early psychobiographies were studies of Hitler, Herman Melville, and Gandhi. There were also psychological interpretations written of Goethe, Vincent Van Gogh, Shakespeare, Emily Dickinson, Henry James, and Dostoevsky. This study of individuals, for the most part, took place up through the late 1930s but then, with the advent of the 1950s and 1960s, focus shifted to psychometrics and the superiority of experimental methods. Ironically, in one of the foremost early texts of experimental psychology, Woodworth (1938) defined psychology as the "scientific study of the activities of the individual … psychology takes the individual as a whole, and describes his activities" (p. 3). This very much sounds like a call for psychobiography.

For Murray, the life history of the individual was the unit of study that psychologists needed to concern themselves. Murray believed that mainstream psychologists of his time were overly concerned with the periphery of sensations and perceptions that added nothing to the knowledge-base of human understanding. Murray was focused on understanding the emotions, feelings, purposive intentions and drives of the individual. For him, this was personality psychology. It was this focus on the study of the individual that eventually prevented Murray from attaining tenure while at Harvard. Murray, in his 1938 text, *Explorations in Personality*, stated that the portrait of a personality was a biography since the notion was generally accepted that the history of the personality is the personality.

Contemporary Contributions to Psychobiography

In 2013, Runyan wrote a chapter on psychobiography and statistics. In this work, Runyan discussed some of the recent works that he felt excelled and which included discussions of individual psychobiography with relevant social, cultural, and historical contexts. Among these notable works is *The Handbook of Psychobiography* by Schultz (2005) which included psychobiographies of psychologists such as Freud, Gordon Allport, Erik Erikson, and S. S. Stevens (founder of Harvard's Psycho-Acoustic Laboratory). It also has sections on "Psychobiographies of Artists" which included Elvis Presley, Sylvia Plath, J. M. Barrie, and Edith Wharton. Political figures, such as Osama Bin Laden, Saddam Hussein, and George Bush, were discussed. It also included other personalities such as Jack Kerouac, Truman Capote, and Diane Arbus. This is an exceptionally readable handbook with insights offered as to how psychobiography can be done more soundly, more perceptively, and more valuably.

William Todd Schultz is a leader in the areas of psychobiography who both edited and contributed to the 2005 Oxford Press edition of *The Handbook of Psychobiography*. In this text, Schultz stated that "One seeking mind, armed with theory and research, directed at the details of another – that is psychobiography....It puts the person back where she should be in personality: front and center, the most moving target imaginable" (p. 3). Schultz goes on to say that there are really two reasons that psychologists should pursue psychobiographies: (1) to clearly know another person and (2) to know ourselves. He asserts that psychobiographies produce hypotheses and insights which can then go on to be tested against other larger groups of people. It is from the study of these single lives that the impetus for inferential research can arise. Just as the single case in neuroscience spurs inquiry, so too can the single case in psychobiography.

The hunches and insights produced by psychobiographies lead to theories and hypotheses which in time can then be formally tested in personality psychology. Psychology began this way with Freud, Jung, Piaget, Maslow, Murray, Allport, and others examining individual lives and in turn devising theories that were applicable to all people.

Characteristics Features of Good Psychobiography

So what makes good psychobiography? According to Schultz (2005), the markers of good psychobiography include cogency, narrative structure, comprehensiveness, data convergence, sudden coherence (where interpretation brings the initially incoherent into coherence), logical

soundness, consistency, and viability. Within the narrative itself, conclusions follow naturally from the presentation of the data. The data comes from multiples sources and converges, triangulates, to support and illuminate central ideas. The narrative is free of contradictory explanations and illogical conclusions. The conclusions fit with the data, and at its best, offer elucidation where there was none. The hypotheses can be held to the light of falsification and stand true. The best psychobiographies leave the reader feeling won over, persuaded by the presentation of the narrative. In addition, the suppositions fit with the general knowledge supplied by more experimental personality psychology. This is what draws nearly every psychologist to the field: people and the understanding of what makes people tick. This is not to say that other forms of research in personality psychology are wrong or should be avoided, but that personology is one legitimate form of developing an understanding of personality, one of the central objectives of personality psychology.

Prior to beginning one's own writing, the methodology of psychobiographical research should be investigated. Some of the classic as well as more recent psychobiographies should be read. While the classic psychobiographies often are considered flawed because of author bias and the lack of rigorous research methods, they will still have much to teach you. Freud's profile of da Vinci would be a good choice here. Erickson's work on Luther and his work on Gandhi, which won a Pulitzer Prize in 1970, would be exemplary recent examples.

Case Study Method

Psychobiographies are just one type of case study. Case studies have been both a teaching tool and a research methodology – two very separate and distinct applications. Case study *research* has its own design, methods, and analytical techniques. It can focus on a single individual, a group, organization, or institution. The subject of the case study in psychology is often an individual, whereas outside of psychology you are more apt to see the subject be an organization, group, or institution. It focuses on *individual data*, however, as opposed to grouped data and is limited by the inability of the researcher to manipulate variables.

Case study research in psychology has three distinct qualities (Yin, 2014): making an in-depth inquiry, studying conditions over time, and covering contextual conditions. This third quality, contextual conditions, is actually one of the strengths of this type of research. To fully understand the subject of study, you need to understand the contextual issues surrounding it. Consider the psychobiography. It is important to examine the friends, community, work, family, and cultural contexts in which this individual's life is embedded. As you contemplate these real-life concerns, they will not all fall into easy categories. This blurring of categories, and blurring between your subject and their world, is another strength of case study research (Yin, 2014) and may provide new insights that were never anticipated. The reasons psychologists use case study methods fall into three categories: description, explanation, and evaluation (Small Group Instructional Diagnosis would be a type of evaluative case study). When case study research is done correctly (using protocols, and triangulating data, and increasing reliability through use of databases and a chain of evidence) it is rigorous and demands a great deal of effort. Done correctly, it is a very powerful tool.

To be exemplary, a case study must be well defined and avoid artificially controlled non-research constraints. If you do not have the time or money for this, limit your design from the outset. Be sure that your data collection process is complete. Continue to gather and analyze data until you reach a saturation point where new insights are no longer being identified.

While analyzing data, rival explanations must be considered. The research must clearly show that all evidence was considered, not just the evidence that supported the initial point of view. At the same time, avoid allowing the pressure of the volume of data to try to make one's case. Be clear on the validating steps taken, without belaboring the issue. One needs to be concise, parsimonious, and still entice the reader to continue reading. This takes talent, and numerous rewrites. If one can balance the skills of the scientist *and* the novelist, one will have been successful.

Summary Evaluation of the Psychobiography and Case Study Methods

Strengths

For these two approaches to studying personality, the primary strengths are those of depth and uniqueness. By utilizing psychobiography, we can undergo an in depth study of a single individual or case – a major strength of these approaches. It allows us to examine individual differences, to understand the impact of context, and to examine in-depth the patterns of behavior within an individual across time. Another advantage with the case study and psychobiographical approaches is that it allows us to study cases and events that are rare. Some events are so rare, such as the survival of Elisabeth Fritzl or the cannibalistic murders of Jeffrey Dahmer, that they *must* be studied when they do occur, and in as much depth as possible.

Limitations

The primary limitations of these approaches are those of generalizability and bias. While it is certainly true that you cannot generalize from the psychobiography of the individual to the general public, it is equally true that you cannot generalize from the nomothetic research to understand the uniqueness of the individual. As long as the researcher and the reader keep in mind the purpose for each approach, it does not have to be considered an insurmountable limitation.

Bias potentially comes from two directions: researcher bias and subject bias. Researcher bias is the tendency for the scientist to gather and interpret data in a way that is consistent with their assumptions. For example, when studying the personalities of the presidential candidates, a researcher who adheres to Adler's birth order theory, may place undue emphasis on the candidates' birth order. Subject bias, on the other hand, is where the individual being interviewed or surveyed may distort the information by either intentionally withholding or skewing information, perhaps out of embarrassment, or by trying, either intentionally or subconsciously, to "fill in the gaps" of distant events.

Conclusion

By investigating individuals in personal, in-depth detail to achieve a unique understanding of them, these idiographic approaches to personality study (psychobiography and case study methods) can make unique and valuable contributions to our understanding of personality.

Factor Analysis in Personality Research

Shay Luu[1] and Amanda ElBassiouny[2]

[1] *Howard University*
[2] *California Lutheran University*

Factor analysis is a statistical technique that simplifies data while investigating the relationships between several variables and attempts to determine whether a pattern of correlation between a number of variables can be explained by underlying dimensions, known as factors. Factor analysis can be used for scale/questionnaire construction, scale/questionnaire verification, and examining the structure of a psychological construct.

The first step in factor analysis is creating a correlational matrix for each variable, that summarizes the correlational coefficients for all variables. Second, the matrix needs to be examined for any patterns that may emerge which is done through the use of a statistical package. When a potential factor is identified, the next step is to compute a correlation between each identified factor and each of the original variables. Variables with the highest factor loading have the strongest association with the factor and play a larger role in defining the factor's dimensionality. Lastly, the final step is to name the factors.

Factor analysis concisely describes large amounts of data by summarizing the correlational relationships between and among many variables simultaneously (Goldberg & Digiman, 1994). By doing so, relationships and patterns are easily interpreted and understood. This can be employed to confirm a hypothesis through Confirmatory Factor Analysis or to reveal insights into the factors through Exploratory Factor Analysis that had not previously been considered. Exploratory Factor Analysis allows multiple perspectives to be considered which may aid in establishing the underlying structure that best explains the underlying factor.

Factor analysis has allowed personality psychology researchers to develop a deeper understanding of difficult-to-measure constructs leading to developments in theories of personality. Factor analysis originated with Charles Spearman's attempts to develop a theory of intelligence; Spearman's bi-factor model of intelligence stated that mental ability was determined by the g-factor, a factor of general ability, and an s-factor, a specific component of variation suited to each assessment (Spearman, 1904, 1927.) Multiple factor analysis developed as it became apparent that a bi-factor theory was not suitable to describe a

battery of psychological tests, which led to a blossoming of work on theories and mathematical principles in which Spearman's bi-factor theory was discarded and the development of multiple factor analysis (Harman, 1976.) Multiple factor analysis expanded upon Spearman's design by allowing multiple factors to be considered simultaneously using the same methodology of selecting highly correlated variables to be identified as a factor.

In personality psychology, factor analysis is most notably used in the development of personality theories. Typically, personality theories are developed using the lexical approach. The lexical approach creates natural descriptors and a standard vocabulary to describe varying dimensions of personality (John, 1990). Gordon Allport began developing a list of lexical personality and trait descriptors in 1936, which predisposed personality psychology toward a lexical approach in describing personality dimensions. Raymond Cattell (1950) built upon the previous work of Allport, distinguishing between surface traits, characteristics that are observed in a given situation and source traits, underlying factors which determine surface responses. Cattell gathered a large variety of data such as life records (L-data), self-report questionnaires (Q-data), and projective tests (T-data.) Cattell then established an intercorrelational matrix which summarized how strongly each variable was correlated with every other variable. At this juncture, Cattell identified potential clusters of variables that may be potential factors, identified as source traits, in Cattell's theory. Potential clusters of variables are identified by their factor loading, which is calculated with the aid of a computer and a statistical software package. The magnitude of the factor loading determines how strongly associated a variable is associated with a factor. Finally, Cattell identified 16 factors, source traits, that he considered fundamental to personality (1966) and used them as the basis for of his Sixteen Personality Factor Questionnaire (16PF).

Cattell's theory of personality provided the necessary theoretical underpinnings for the development of the popular Five Factor personality theory, colloquially known as the Big Five (McCrae and Costa, 1987, John 1990). While there is agreement that there are five dimensions shaping human personality, there is still some debate on the nature of the dimensions. The most commonly agreed-upon factors are Neuroticism, Extraversion, Openness, Agreeableness, and Conscientiousness. It should be noted that scholars do not always use the same terms either. The Big Five originated from two separate approaches to identify basic factors in personality. One approach was the lexical approach that has been replicated across different languages such as Japanese, Chinese,and German (Digman, 1990). The other approach employed the use of factor analysis of personality questionnaires, which led to an explanatory hypothesis, the Five Factor Model (FFM) about dispositional traits that are inherited (John & Robins, 1993). While both utilize different approaches, they both support five factors of personality; but the FFM attempts to advance interpretation regarding the traits of the Big Five (McCrae & Costa 1987) whereas the Big Five merely provides a description. However, the FFM asserts that personality can be described in terms of five broad categories in terms of scores on the measure of the broad category and that differences among people in these dimensions are stable over time partially due to a genetic basis and in part to an internal mechanism, not yet known.

Factor analysis is used extensively by personality psychologists as a research tool. It is used in at least four related ways: as a data reduction technique, as an exploratory technique to examine the underlying structure of correlated data, as a confirmatory hypothesis-testing tool, and is also used to summarize the relationships of multiple correlated variables.

Meta-analysis in Personality Research

Lauren B. Nickel and Wenting Mu

University of Illinois at Urbana–Champaign

Meta-analysis is a form of systematic review in which the results of multiple individual studies are combined to estimate the summary effect size for the relationship in question. To calculate the summary effect size, researchers find a weighted mean of effect sizes across all studies included in the meta-analysis. How the weighted mean is calculated depends on factors such as characteristics of or assumptions about the collection of studies. Though some work with combining results had been done in prior decades, meta-analysis took off in earnest in the 1970s. Gene V. Glass (1976) introduced the term "meta-analysis" into the research lexicon, and he and his colleague Mary Lee Smith (1977) published a meta-analysis that found that psychotherapy is indeed effective. In the following decade, Larry V. Hedges and Ingram Olkin (1985) published a book on meta-analysis that formalized the statistical methods, as well as providing a foundation for advances that have come since. Since the 1970s, meta-analysis has become an increasingly common form of analysis.

Meta-analysis is a useful form of analysis because it can be used to answer questions about the relationship between variables such as whether or not an effect exists and the magnitude of the effect. Knowing the effect size can be more important than determining if the effect is statistically significant. Researchers may come across studies where the results contradict one another, often because the modal sample sizes are small in many studies. A comprehensive meta-analysis of an area of interest may help to overcome the variability that comes with highly variable, single studies. Meta-analysis may also be used to answer more complicated questions, such as how the results of a given study can be understood within the area of interest. The meta-analytic results may suggest a consistency (or lack thereof) among the studies; if there is consistency, then one can accurately estimate the effect size, but if there is inconsistency, one can look at the variation and seek to further understand possible sources of the variation. Additionally, meta-analysis may be used to test a hypothesis, similar to what the individual studies themselves are doing.

Conducting a Meta-analysis

Meta-analysis is a multi-step process. Researchers start by specifying their research question as clearly as possible, as a means of guiding themselves through the rest of the meta-analytic process. Once the area of study has been clarified as fully as possible, the next step consists of searching the literature for relevant studies. This search should be as thorough as possible, including both published and unpublished research, from a variety of sources, not just electronic databases. Once they feel they have exhausted their literature search, researchers can begin coding, or documenting information about, the studies they have collected. Two types of information are coded for each study: (1) moderators, or characteristics of the study, and (2) effect sizes, or the study's findings. Moderators may come in many forms and depend on the nature of the area under study; they may include information about the sample (e.g. gender, clinical vs. nonclinical), information about the study (e.g. quality of the study, type of intervention), or information about the variables under investigation (e.g. the measure used to assess the variable). The collection of studies should be coded independently by multiple individuals to ensure greater reliability. Following coding comes data analysis. A wide variety of statistics will be found in the collection of studies, including, but not limited to, standardized mean differences, odds ratios, and correlation coefficients; these can be converted from one to another to derive a single common effect size. Researchers calculate the weighted mean effect size and distribution; depending on the nature of the studies included in the meta-analysis, researchers may make different assumptions about the effect size and heterogeneity, which guides the choice of model (fixed-effect, random-effects, or mixed-effects) for calculating meta-analytic statistics. Additionally, prior to computing the mean effect size, the individual effect sizes may be corrected for bias. After completion of data analysis, researchers present their findings in a report.

Interpreting the Meta-analysis

Effect size is the favored metric used by researchers when conducting meta-analysis; it indicates the magnitude and direction of the relationship between two variables. They can be divided into three categories: (1) correlations, such as the Pearson correlation coefficient r; (2) mean differences, either raw (D) or standardized (d or g), and (3) contingencies, such as odds ratios or risk ratios. The choice of effect size used in a given meta-analysis depends on what type of relationship is being assessed. When coding the collected studies, researchers will find that the results will contain a variety of types of statistics that are not the effect size of choice for the meta-analysis, such as means, chi-square statistics, t-tests, and F-tests, as well as other types of effect sizes. Regardless of the type of results presented, they can be converted to a common effect size so the results from multiple studies can be combined, or an effect size should be chosen such that it can be calculated from the information present. Effect sizes can also be calculated from p-values if the authors have provided the exact p-values associated with a finding.

   Prior to combining the effect sizes calculated from the studies being used, researchers may consider corrections to them for various reasons. Differences in research design may affect the magnitude of the effect size, and type of research design could be used as a

moderator. Additionally, if multiple effect sizes from one study are being included, non-independence of these estimates may be an issue; to alleviate this, researchers may choose a single effect size randomly from these studies for inclusion in the overall effect size. Also, there may be concerns associated with measurement or statistical analyses, such as sampling error, unreliability, range restriction, or dichotomization of continuous variables, which may result in a lower effect size. Proponents of effect size correction argue that those procedures give a more accurate estimate of the true effect size. Opponents to correction, such as Rosenthal (1991), argue that correction prevents researchers from learning what the relationship between two variables is in practice, rather than what it might be in an ideal world.

When calculating the statistics associated with a meta-analysis, researchers may use one of three models: a fixed-effect model, a random-effects model, or a mixed-effects model, depending on their assumptions about the relationship being studied. A fixed-effect model assumes one true effect size for the set of studies collected; any differences among studies are due to sampling error. Because the true effect sizes across studies are assumed to be equal, they are considered homogeneous. However, in other cases, the true effect sizes are heterogeneous, i.e. they are not equal to one another. There may be moderators that influence the effect sizes, in which case a fixed-effect model with moderators may be appropriate. A random-effects model may also be used when heterogeneity is indicated. A random-effects model assumes a distribution of true effect sizes; the calculated mean is an estimation of the mean of this distribution, and the variance indicates the amount of random heterogeneity. Another option is a mixed-effects model, where differences in the true effect sizes are due to both moderators and random heterogeneity.

To test for heterogeneity, researchers may compute the Q-statistic. Q uses the chi-square distribution with $k - 1$ degrees of freedom, where k is the number of studies included in the meta-analysis; if Q is larger than the critical value according to this distribution, it is indicative of the presence of heterogeneity, though not the magnitude. To determine the amount of heterogeneity present, one may calculate I^2, the ratio of between-study variability of effect sizes to total variability of effect sizes, calculated as a percentage.

Some Concerns with Meta-analysis

Publication bias is a concern for meta-analysts, as studies with large effect sizes are more likely to be published than studies with small effect sizes, and any such bias will be reflected in the results of the meta-analysis. To combat the potential effects of this bias on the results of the meta-analysis, a comprehensive search of the field's literature is necessary, including both published and unpublished studies.

To further address concerns about the inclusion of biased studies, researchers may also look for evidence of bias, using methods such as funnel plots. A funnel plot is a scatter plot where studies' sample size and effect size are plotted against one another; the expectation is that small studies will have a wide range of effect sizes, and as the sample size increases, the variation in effect sizes will decrease, clustering around the estimated mean effect size and resulting in a funnel-shaped graph. If the funnel is symmetric, that provides evidence for a lack of publication bias; if the funnel is asymmetric, there are

likely studies missing, most likely small studies with null results or results contrary to what the researchers hypothesized.

A formal technique of testing whether the funnel plot is symmetrical is the trim-and-fill test (Duval & Tweedie, 2000), which consists of two steps and uses the funnel plot. In the first step, researchers "trim" the studies that contribute to the asymmetry of the funnel plot and find the center of the trimmed funnel plot. In the second step, the trimmed studies are reintroduced to the funnel plot, along with the imputed values of the missing studies, around the center; the mean effect size is calculated from the filled funnel plot. This procedure can result in more accurate estimates of both the mean effect size and heterogeneity.

The Egger test (Egger, Smith, Schneider, & Minder, 1997) also tests the asymmetry of the funnel plot using a linear regression equation. The standard normal deviate (SND) is calculated by dividing the effect size by its standard error (ES/SE), and the precision is calculated as the inverse of the standard error (1/SE). The SND is regressed onto the precision (SND = β_0 + β_1(precision)). If there is no asymmetry in the funnel plot, the regression line will run through the origin when the standard normal deviate equals zero. If asymmetry exists, the regression line will not run through the origin. β_0 acts as a measure of asymmetry. If there is none, β_0 equals zero; if asymmetry exists, β_0 does not equal zero, and a greater value indicates greater asymmetry. β_1 provides an indication of the size and direction of the effect.

Multiple Regression in Personality Research

Khairul Anwar Mastor

Universiti Kebangsaan Malaysia

Introduction

Multiple regression or multiple linear regression (MLR) is a general statistical method to examine causative relationships between a dependent (criterion) and a set of independent (predictor) variables. Its main function is prediction. It determines which independent variables are significant predictors. The adjective "multiple" denotes that there could be two or more predictors. In psychological research work, especially personality-social related areas, there is more than one possible variable determining psychological outcomes. Personality variables such as personality traits and other categories of individual differences are commonly involved in explaining human thoughts, feeling, and behavior. Since prediction is pivotal in personality work, multiple linear regression is basically the most common and unavoidable form of analysis in personality and individual differences research.

In this section, a brief explanation of the following is covered: the basic principle of MLR, how to conduct the analyses, the multicollinearity issue, and the MLR application in the study of personality and social context. Toward the end of this section, future direction of the MLR in research, theory and methodology is briefly mentioned.

Basic Principle of MLR

The basic principle of MLR in social-personality research is to predict effects or impacts of change observed in the dependent variable caused by independent variables. Thus, MLR is used to predict pattern of changes – for instance, will there be any personality trait or state changes after six months of marriage or after undergoing military training for more than one year?

To begin the analyses, the existence of linear association between the independent and dependent variables must first be established. If they are linearly related, each independent

variable's predictive strength and direction would then be analyzed. This association is in the form of prediction – usually presented in the following equation:

$$y_i = \beta_0 + \beta_1 x1,I + \beta_2 x2,I + \cdots + \beta_k xk,i + ei,$$

where y_i is the dependent variable and $x1$, $x2$, i, ... , xk, i are the k predictor variables. Each of the predictor variables must be numerical or quantitative. In personality research, it may come in the form of mean scores of latent variables. The magnitude of coefficients $\beta_1, \beta_2, ..., \beta_k$ represent the strength of the Coefficient of Determination or measure of the predictive power of the independent variables. The sign (+ or –) of β indicates the direction of the relationship whether positive or negative. In every analysis, the objective is to get the best fit regression equation. Model fit is important – adding relevant independent variables will always increase its statistical validity – it will always explain a bit more variance (expressed by R^2). This equation can be used to predict the value of target variables based on given predictor variables.

Procedure of Using Multiple Regression

Multiple linear regression analysis is done through sequential stages. According to Hair et al (2018), there are six stages to follow in the MLR analysis.

1 Setting the Objectives of the Analysis

This is the initial step during data analysis where the research problem is determined. If the research problems and objectives are to identify potential predictors among independent variables on dependent variable, then MLR is the right data analytical tool. In most analyses, the attempt is to maximize the predictive power of a set of independent variables upon dependent variables. Selection of the dependent and independent variables included in the prediction should be based on sound theoretical considerations.

2 Designing Research of the Analysis

The next step is to determine the nature of independent variables and sample size. Sample size is considered most important since it will have an effect on statistical power and accuracy of the significant testing. Small sample size (i.e. $N < 20$) may be more appropriate for simple regression analyses. It is recommended to identify the optimum sample size which is most effective (Pituch & Stevens, 2016) for getting reliable results.

3 Assumptions of the Analysis

Several assumptions must be met for both independent and dependent variables prior to the analysis.

a) Both independent and dependent variables are of quantitative or continuous variables.
b) Linearity – the relationships between the independent and dependent variables should be linear.

c) Normality – data must be normally distributed. If data is not normal, a non-linear transformation such as log-transformation can be imposed although transformation can also introduce effects of multicollinearity. Linear regression is very sensitive to outliers. It can have a significant impact on the regression line and eventually the forecasted values.

d) Independence – predictors should not be associated with each other, thus, multicollinearity should be minimal or absent.

4 Estimating the Regression Model and Assessing Overall Model Fit

To get the best estimation of the regression model, the method of data selection should be selected either using a forward or backward elimination, a trial-and-error estimation procedure, or a stepwise estimation. Then, the statistical significance of the overall model in predicting the dependent variable is determined – finding the best estimates of the coefficients is often called "fitting" the model to the data.

5 Interpreting the Regression Variates

The output of the analyses normally consists of the coefficient of estimates, R and R square values, standard errors, and also β coefficients. Estimates of each β coefficient and its "standard error" are used to calculate values for each observation and to express the expected change in the dependent variable for each unit change in the independent variables. Beta coefficients are used as a guide to the relative importance of individual independent variables in the model.

6 Validation of Results

This is the final stage of the regression analysis in which the generalizability and predicting ability of the model are re-tested. A new sample can be taken to test whether the outputs represent the general population (generalizability) and its appropriateness for the situations (predicting ability). In addition, we should also look at the matching and relevance of the data with the existing theoretical model or a set of previously validated results on the same topic.

Multicollinearity

One of the challenges to provide best estimation using MLR is multicollinearity. Multicollinearity exists whenever two or more predictors are moderately or highly correlated in a regression model. It is indicated by the value of correlation between two variables surpasses 0.80 (Hair, 2018). Such a problem might be due to data problems, not a problem of model specification. It has a substantial effect on the results of regression model since it will not be possible to separate the effects of these two predictors. One of the tests to assess the existence of multicollinearity is the variance inflation factor (VIF). VIF is the variance inflation factor of the linear regression defined as $VIF = 1/T$. The smaller the value of VIF, the less likely data has multicollinearity. On the other hand, if VIF is bigger than 10, there is an indication for multicollinearity to be present.

The Major Uses of MLR in Personality Research

Three major uses for multiple linear regression analysis are (1) causal analysis, (2) predicting an effect, and (3) trend forecasting.

First, causal analysis normally uses the MLR to determine the predictive strength of the independent variables. For example, Sorokowska et al. (2016) found that social exhibitionism and extraversion predicted the frequency of online selfie-posting in men and women. In another study, Malesza and Ostaszewski (2016) discovered two dark personality traits, narcissism and psychopathy, as significant predictors of adolescent risk behaviors.

Second, MLR can be used to predict effects or impacts of changes. Matz, Gladstone, and Stillwell's recent work (2016) on the impact of personality traits on achieving happiness found that whenever one's personality trait is matched with the pattern of spending money, happiness and positive affects increase.

Third, multiple linear regression analysis predicts trends and future values. The study by Sobrinho et al. (2016) on predicting suicidality is a good example. They found that perceived parental rejection demonstrated direct and indirect relationships with suicidality, and self-criticism and neediness each had indirect associations with suicidality in a five-month period.

Current Use of Multiple Linear Regression in Research

Use of MLR in personality research has been continuously increasing. In November 2019 a search via the SCOPUS data base was made, to date, more than 244,738 studies used MLR in various fields including 20,721 studies in psychological fields (of which 8,589 articles are in the personality research area). Since 1980, 189,602 articles in the Web of Science data base used MLR, 7,862 in psychiatry and 2,519 in psychology. These data indicate that multiple regression has been widely used in personality research as well as in other areas of studies.

Since the basic principle of MLR is to predict changes in the dependent criterion affected by several independent variables, the use of this principle has also been extended to more advanced analytical methods. Its predictive function allows flexibility of MLR in different analysis procedures such as in mediation and moderation analysis. It is also used in structural equation modeling (SEM) and hierarchical linear modeling (HLM) or multilevel modeling (MLM) which adopt the predictive function of MLR in different forms. In MLM, for example, effects of independent variables are examined on two or more different levels, intra/within and inter/between individual.

Future Use of MLR

Multiple regression analysis continues to be an important tool for modeling and analyzing data. To date, the use of the analyses has been extended in much personality and individual research, notifying the fundamental role and predictive utility of MLR.

Given the flexibility of the multiple regression and its relative simplicity, it is predicted that the use of multiple regression analysis in personality research will continuously increase – despite the emergence of many advanced and highly complicated data analyses techniques – in the long quest to understand human individual differences and functioning through the study of personality.

Path Analysis in Personality Research

A. Alexander Beaujean and Sonia Parker

Baylor University

Sewell Wright developed the method of path analysis as a way to study causation in agriculture and genetics. He thought that simply computing correlations between variables did not represent their actual causal nature. Nonetheless, he did think it was possible to decompose the correlations among variables into their underlying causal relationships. This is the underlying principle of path analysis: "The correlation between two variables can be shown to equal the sum of the products of the chains of path coefficients along all of the paths by which they are connected" (Wright, 1920, p. 115).

Path analysis largely stayed in the fields of biology and genetics until it was brought into the fields of economics and sociology. From there, it was largely introduced to the field of psychology by Karl Jöreskog (1973) through his linear structural relations (LISREL) models.

Path Diagrams

To represent the ostensible underlying causal relationships among variables, Wright developed path diagrams. Path diagrams express the equations relating a system of variables using geometric shapes and arrows. These are shown in Figure 1. When the elements in Figure 1 are correctly combined in a path diagram, then the algebraic relationship between the variables is completely specified.

There are three steps involved in creating a path diagram. First, lay out all the variables (i.e. squares, circles, and triangles) in the model. Second, specify the relations (i.e. arrows) among the variables. Third, determine whether the parameters associated with a given path/arrow need to be fixed at specific values or estimated from the data.

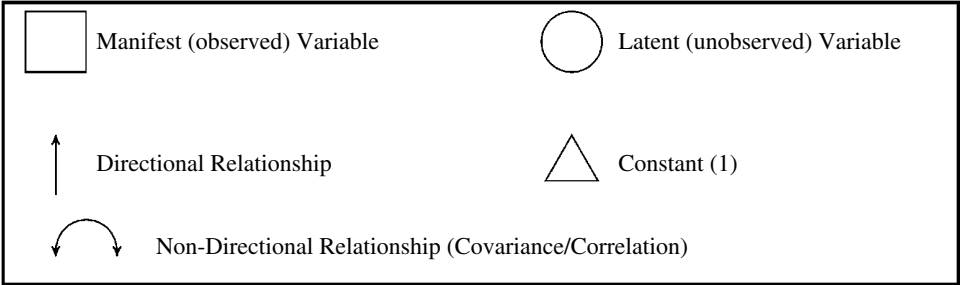
Variables in a path model can be categorized into one of two types: those that are without a direct cause (*exogenous*) and those with a direct cause (*endogenous*). Endogenous variables always have an attached error term associated with them, which represents the discrepancy between the observed values and the values predicted by the model. Because the


Figure 1 Path diagram elements.
Figure 2 Path diagram for a multiple regression with two predictor variables from Equation 1.

error terms, by definition, represent something unexplained by the model, they have no direct cause within the model so are exogenous; moreover, these error terms are not directly measured, so they are latent. While endogenous variables are never connected to non-directional (i.e. double-headed) arrows, their error terms can covary with other variables.

As an example, say we have three standardized variables: two predictors (X and Z) and one outcome (Y). One might think, for example, of X and Z as representing professors' levels of Agreeableness and Charisma, and Y representing students' Ratings of Effectiveness. Equation 1 shows one possible structural equation of how the variables might be related.

$$Y = bX + cZ + dE, \qquad\qquad 1$$

where E is an error/residual term with a mean of zero. Equation 1 also happens to be a multiple regression. Thus, it hypothesizes that professorial personality traits are directly related to student perceptions of professorial effectiveness.

The analogous path diagram for Equation 1 is shown in Figure 2. It contains three squares and one circle. The squares represent the two predictor variables and one outcome

variable while the circle represents the error term associated with the outcome. The model contains three single-headed arrows (b, c, and d) that point to Y. These arrows represent the three terms that are added together on the right-hand side of Equation 1.

Figure 2 contains four double-headed arrows. All exogenous variables and all error terms need to have a double-headed arrow to represent their variance. In Figure 2, arrows e and f represent the variance for variable X and Z, respectively. The double-headed arrow for E (h) represents the error variance (i.e. the variance in Y that is unexplained by X and Z). The double-headed arrow between X and Z (g) specifies the potential covariance between these two predictor variables. If this arrow were excluded, then the model would specify that the predictor variables are independent of each other (e.g. professorial Agreeableness and Charisma are unrelated). Because all variables are standardized, there is neither an intercept term in Equation 1 nor a triangle (constant) in Figure 2. If the variables were not standardized, then the path model would include a triangle pointing to the Y variable to represent the intercept.

Estimating Values for the Paths

Wright developed a set of rules for how to estimate values for a path model's coefficients by tracing the paths within it. These *tracing rules* are simply a way to estimate the covariance between two variables by summing the appropriate connecting paths. A version of these rules is given in Figure 3.

- Trace all paths between two variables (or a variable back to itself), multiplying all the coefficients along a given path.

- You can start by going backwards along a single-headed arrow, but once you start going forward along these arrows you can no longer go backwards.

- No loops. You cannot go through the same variable more than once for a given path.

- At *maximum*, there can be one double-headed arrow included in a path.

- After tracing all the paths for a given relationship, sum all the paths.

- The mean of a variable is found by tracing all paths from it to the constant, and then adding all values. The paths:

    o can only go through directional arrows, and

    o can only go backwards along an arrow

Figure 3 Tracing rules for a path diagram.

Table 1 Correlation matrix to accompany Figure 1.

	X	Z	Y
X	1.00		
Z	.20	1.00	
Y	.70	.30	1.00

To estimate the relation between X and Y in Figure 2, find all the permissible pathways from X to Y. These paths are b and gc. Likewise, all the permissible pathways from Z to Y are c and gb. The covariance of Y with itself (i.e. the variance of Y) consists of the paths that both start and end at Y: $beb = b^2e$, c^2f, cgb, bgc, and dhd. For model identification, either d or h needs to be constrained. Setting d equal to one makes the path to and from Y: $1h1$ or just h. The sum of paths that go through X and Z represents the amount of Y's variance that X and Z explain (i.e. R^2): $b2e + c2f + cgb + bgc = R^2$. Because d was set to equal one, h represents all the error/residual variance (i.e. $1 - R^2$).

Estimating numerical values for the paths is a straightforward task after calculating all the variables' variances and correlations (and means, if applicable). It simply involves setting the appropriate path combinations equal to the correct value. Since the variables' variances and correlations are already known from the data, some of the path values are automatically known (e.g. e, f, g in Figure 2). The remaining path values can be calculated by setting up a system of equations. If the number of known values (i.e. variances, correlations) are equal to, or greater than, the number of unknown path values (which is the case for Equation 1/Figure 2), then solving these equations should produce unique estimates for the paths. If there are more unknown paths to estimate than there are known values, then the model is underidentified and there will not be unique values for the paths.

Some example correlations to accompany the path model in Figure 2 are given in Table 1. From this data, the following path values are automatically known: $r_{XZ} = g = .20$, $s_X^2 = e = 1.00$, and $s_Z^2 = f = 1.00$. As the correlation between X and Y is .70, the sum of all paths from X to Y has to equal this value, i.e. $r_{XY} = .70 = b + gfc$. The values for g and f are already known, so the equation simplifies to: $.70 = b + (.20)(1)(c) = b + .20c$. A similar equation can be set up for the correlation between Z and Y: $r_{ZY} = .30 = c + geb = c + .20b$. The correlations between Y and X and between Y and Z make up a set of two equations with two unknown values: $.30 = c + .20b$ and $.70 = b + .20c$. When solved, $b = .667$ and $c = .167$.

The last path value to estimate is h. This value can found just like b and c, although the equation is more complex: $s_Y^2 = 1 = b^2e + c^2f + bgc + cgb + h = .667^2 + .167^2 + (.667)(.20)(.167) + (.167)(.20)(.667) + h$. After completing the arithmetic, this simplifies to $h = 1 - [.667^2 + .167^2 + 2(.667)(.167)(.20)]$, which makes $h = .483$.

Extensions

Path models are not confined to only representing regression equations. They can also represent multivariate models, such as those required for mediation models, confirmatory

factor analysis, and canonical correlations. Moreover, path models can be used as the building blocks for general structural equation models. Some examples of more complex path models are shown in Figures 4, 5, and 6.

Size Effects in Personality Research

Lauren B. Nickel

University of Illinois at Urbana–Champaign

Recently, there have been efforts to move away from null hypothesis statistical testing (NHST) and move toward estimation in psychology research, including using effect sizes and confidence intervals to report results. One reason is that effect sizes provide more information about the data than *p* values do; whereas *p* values tell researchers that a result is statistically significant or not, effect sizes provide information about the magnitude and direction of the effect. The most up-to-date edition of the *Publication Manual* of the American Psychological Association (2010) calls for reporting effect sizes and confidence intervals alongside any results from NHST as a way of getting the most complete picture of the results. Effect sizes and their corresponding confidence intervals can be compared across similar studies to assess consistency in different samples, as well as precision.

What is an Effect Size?

The definition of effect size can be broad – researchers can think of an effect size as anything that quantifies what they are studying. The term effect size can encompass a wide variety of statistics, ranging from means to correlations to measures of goodness of fit. What an effect size is actually assessing depends on what type of research is being conducted. In experimental research, the effect size can indicate the amount of influence an independent variable has on a dependent variable. In non-experimental research, the effect size can indicate the size of the relationship between two variables.

A good effect size measure possesses four desirable qualities (Preacher & Kelley, 2011). First, the scale used for the effect size measures should be appropriate for the research question; sometimes the scale may be standardized, but other times the scale may be in the measure's original units. Second, the estimate should be reported with a confidence interval. Confidence intervals provide a way of assessing the level of uncertainty associated with a given effect size estimate and are indicative of how much sampling error is associated with the effect size value. Additionally, they provide information about the population

value being estimated with the effect size measure. Third, the effect size measure should be independent of sample size. For this reason, among others, *p* values are not a proper effect size measure. Fourth, the measure should have good statistical properties. It should be unbiased (the expected value of the effect size estimate should be the same as the parameter being estimated), consistent (as *n* increases, the effect size estimates should converge to the population parameter), and efficient (an efficient estimator is stable among the samples being tested).

What Effect Sizes are Used?

As previously mentioned, researchers have a wide range of effect size measures to use in assessing their results. Effect size measures have been categorized in a number of ways; here, they are divided into two categories, unstandardized (or raw) and standardized.

When researchers choose to use unstandardized, or raw, effect size measures, they are using measures such as the mean, median, or difference between two means. They appear in their original units and are interpretable, such as the number of cigarettes smoked each day. They may be used less frequently in psychological research compared to other fields such as medicine; many psychological constructs are more abstract in nature than, for instance, blood pressure. However, Wilkinson and the APA Task Force on Statistical Inference (1999) recommend using unstandardized measures where possible. Other unstandardized measures include the covariance, which may be appropriate when researchers are looking at the association between two variables, and the unstandardized regression coefficient, which estimates the amount of change in the *y* variable for each unit change in the *x* variable.

Researchers may also choose to use standardized effect size measures. These include measures traditionally thought of as effect size measures, such as Cohen's *d*, and are unit-free, which is helpful for comparing effect size values across studies where the variables are measured using different scales. There are two families: the *d* family and the *r* family.

The *d* family contains measures of standardized mean differences and includes measures such as Cohen's *d*, Hedges' *g*, and Glass's Δ. The generic formula for the *d* family measures is the difference between two group means divided by the population standard deviation ($(M_1 - M_2)/SD$). Where these three measures differ is in the standard deviation used. Cohen's *d* uses a pooled standard deviation estimate for the two groups. Hedges' *g* uses a pooled weighted standard deviation estimate, if the size of the two groups is different. Glass's Δ uses the standard deviation from the control group.

The *d* family also includes dichotomous measures that assess the likelihood of participants belonging to one of two categories. To assess this likelihood, researchers can use three measures, with *p* as the probability of an individual belonging to Group 1 and *q* as the probability of an individual belonging to Group 2. First, they can calculate the difference between two probabilities ($p - q$). Second, they can calculate the risk ratio (p/q). Third, they can calculate the odds ratio ($((p/(1 - p)/(q/(1 - q)))$).

The effect size measures in the *r* family provide information about the strength of the relationship between two variables and can be used with both dichotomous and continuous variables. They are also standardized measures, enabling comparison among related

studies. Correlation coefficients provide information about both the strength and the direction of the association. There are many different types of correlation coefficients, including the Pearson product moment correlation coefficient (r), Spearman's rank correlation (ρ or r_s), and the point-biserial correlation coefficient (r_{pb}). The values of these measures range from -1.0 to $+1.0$.

Also included in the r family are measures of the proportion of shared variance. One commonly used measure is r^2, called the coefficient of determination, which is simply r squared. It indicates how much variance is shared between the two variables as a percentage. A related measure is R^2, the coefficient of multiple determination, and is associated with multiple regression. The values of these measures range from 0.0 to 1.0.

Along with unstandardized and standardized measures, there is another type, termed criterion-referenced measures (Ozer, 2007), which are "tied to some meaningful standard outside the original units." An example of such a measure is based on "percentage of maximum possible," or POMP. POMP scores are calculated using the equation $100 \times$ (Observed score – Minimum score)/(Maximum score – Minimum score). This equation indicates where a given score on the associated scale, as a percent of the maximum possible score.

Interpreting Effect Sizes

Cohen (1992) proposed effect size values that correspond to small, medium, and large effects. When using d, small, medium, and large effects are equal to .20, .50, and .80, respectively; when using r, small, medium, and large effects are equal to .10, .30, and .50, respectively. However, others caution against using Cohen's values as a way of determining what a small, medium, or large effect truly is because this may lead to further rigidity, similar to that seen with p values.

However, interpreting an effect size estimate may take more work than simply comparing it to existing benchmarks. Whether an effect size estimate is small, medium, or large may depend on the area of study. The outcome of interest may direct researchers in the assessment, as well as the effect size values found in previous studies in the same area. When considering earlier studies, researchers can assess the quality of the methodology used in the studies presumably, a study done using high-quality methods will have a more accurate effect size estimate than its low-quality counterpart. Additionally, researchers can look at the significance of the finding – do the results have a theoretical or practical significance? A seemingly small effect size may have important implications for the direction the theory takes or for consequences in the world outside of the study. Small effects may also accumulate over time, resulting in a larger effect than initially expected.

As previously mentioned, the *Publication Manual* (APA, 2010) recommends reporting confidence intervals alongside effect size estimates. Confidence intervals provide information about the precision (or uncertainty) of the effect size estimates and aid in interpretation of these estimates. Confidence intervals are equal to $100(1 - \alpha)\%$, where α is the likelihood of the true value not being included in the confidence interval. Values for α commonly include .05 or .01, resulting in 95% or 99% confidence intervals. They provide a range of values for the population effect size and can be interpreted as the degree of confidence that the population effect size is included in the range; any value within the range is

a possible population value. Confidence intervals will vary in their length from study to study because of the variations in sample standard deviations among the studies.

Where Else are Effect Sizes Used?

Effect sizes are important components used in calculating statistical power and in conducting meta-analyses. Power is the probability of correctly rejecting the null hypothesis when the alternative hypothesis is true; it is equal to $1 - \beta$, where β is the likelihood of making a Type II error, or failing to reject the null hypothesis. Power is generally set to .80. There are three pieces of information that are used in calculating the level of power: (1) α, the significance criterion, which is usually set to .05; (2) N, the sample size; and (3) the population effect size. Power analyses are often used to calculate the necessary sample size. If any three of these pieces of information are available, researchers can calculate the fourth, depending on what variable is of interest.

In meta-analyses, researchers combine the results from studies that investigate the same phenomenon as a form of systematic review. They take the effect sizes found in each study and find the average to approximate the true effect size for the relationship between the variables of interest. Commonly used effect size measures in meta-analyses include correlations, standardized mean differences, and odds ratios.

Structural Equation Modeling in Personality Research

Eric B. Weiser

Curry College

Conceptualization

Structural equation modeling (SEM) is a term referring to a collection of statistical techniques allowing researchers to test theoretical models specifying presumed causal relationships among a number of variables. Its primary purpose is to determine whether a theoretical model successfully explains relationships observed in sample data. Unlike traditional statistical methods such as ANOVA and multiple regression, which estimate parameters from individual cases, SEM estimates parameters from covariances among variables in a data set. Additionally, SEM can model theoretical relations among latent (unobserved) variables, although SEM models need not consist of hypothesized latent variables (Hoyle, 2011; Kline, 2005). In their purest form, SEM techniques enable researchers to test how well sets of observed variables define constructs and how these constructs are related to each other (Schumacker & Lomax, 2016). SEM is sometimes referred to as "causal modeling," "analysis of covariance structures," and "covariance structure modeling"; it is also sometimes referred to as "path analysis" and "confirmatory factor analysis," although both are, in fact, special cases of SEM. Many software programs are available to conduct SEM analyses.

SEM Procedures

A crucial first step in SEM is "model specification," whereby the researcher makes specific predictions regarding how certain variables are causally related (Schumacker & Lomax, 2016). These predictions may be specified in the form of linear equations that specify the theorized causal structure among variables (hence the term "structural equation modeling") or in the form of a pictorial diagram that includes all relevant variables and the directionalities of the theorized causal effects among them. Given the non-experimental nature of SEM, it is crucial that model specification be guided by theory and research, rather than the investigator's own

hunches or experiences. Once a theoretical model is specified, SEM mathematically tests whether the sample data covariance matrix is similar to the covariance matrix implied by the specified model. If the two matrices closely resemble one another, then the theoretical model is supported (i.e. the model "fits" the data); if not, the model may be modified.

Model fit is assessed through various indices indicating whether the theoretical model, as a whole, fits the sample data. If the researcher develops and tests different theoretical models, he or she can determine which of these models best fits the data. SEM models also yield parameter estimates for each hypothesized causal path, as well as significance tests for these estimates.

Key Terms in SEM

A *path diagram* is a pictorial representation outlining the theoretical model, that is, the hypothesized relationships among the variables in the model. Any variable predicted to pre-cede and have a causal influence on some other variable is a *predictor variable*, or *antecedent variable*; any variable hypothesized to be affected by a predictor variable is an *outcome variable*, or *consequent variable*. A *manifest variable* is one that is measured or observed directly, whereas a *latent variable* is neither directly observed nor measured; latent variables are often referred to as *constructs* or *factors*. For example, a respondent's score on the Narcissistic Personality Inventory (NPI; Raskin & Terry, 1988) represents a manifest variable, in that it is a direct measure of the respondent's level of narcissism (see Narcissism, Assessment of).

Alternatively, narcissism can be regarded as a latent variable; it is a construct that is pre-sumed to exist, although it cannot be observed directly. A researcher may record partici-pants' scores on a measure of narcissism, but it is understood that the resulting scores are only approximations of where they stand on this construct. An *endogenous variable* is one whose variability is predicted to be causally affected by other variables in the model, whereas an *exogenous variable* is one that is predicted to causally influence variability in one or more endogenous variables.

Exogenous variables are presumed to be influenced by other variables not included within a theoretical model. A *path coefficient* is a number that represents the magnitude of the effect of one independent variable on a dependent variable. In SEM models, path coefficients are in the form of standardized regression coefficients (β), meaning that they represent the amount of change in an outcome variable (in standard deviation units) associated with a one standard deviation change in a predictor variable, while controlling for other predictor variables (see Multiple Regression in Personality Research). A *mediator variable* is an intervening variable that conveys the effect of a predictor variable onto an outcome variable. In simple terms, a mediator variable is a conduit through which one variable indirectly influences another variable.

Assessing Model Fit in SEM

The most basic way to evaluate how well a theoretical model fits the sample data is the chi-square (χ^2) test. In SEM, the χ^2 statistic provides a test of the null hypothesis that the theoretical model fits the sample data. If $\chi^2 = 0$, the theoretical model perfectly fits the data

(i.e. the implied variance-covariance matrix is equal to that of the sample data). Hence, small χ^2 values and concomitant large, non-significant p values suggest the theoretical model adequately represents the hypothesized relationships among the variables in the sample data.

Although the χ^2 test can be a useful index, it has fallen into disfavor because it can be influenced by such things as departures from multivariate normality and sample size (Hoyle, 2011; Schumacker & Lomax, 2016). As such, other fit indices should be considered in evaluating model fit. Some of these include the normed fit index (NFI), goodness-of-fit index (GFI), adjusted GFI (AGFI), and Tucker-Lewis Index (TLI). Values on these indices may range from 0 (no model fit) to 1 (perfect model fit), with values over .90 reflecting good model fit. In addition, it is advisable to review R^2 values for all endogenous variables in the model. R^2 values indicate the percent of the variance explained in endogenous variables independently by the predictor variables. In SEM, R^2 values are interpreted as they are in multiple regression, in that they may range from 0 to 1, with higher values indicating greater variance explained. Large R^2 values for each endogenous variable suggest that the theoretical model demonstrates acceptable fit to the sample data. Finally, it is also necessary to examine the individual path coefficients and if they are significant.

SEM: Three Cases

Three cases below are intended to illustrate the basics of SEM. In the figures that follow, rectangles represent manifest (i.e. measured) variables, and ovals represent latent variables (i.e. constructs); single-headed arrows represent direct unidirectional causal effects as hypothesized by the researcher, and double-headed arrows connecting two variables represent correlations between variables.

Case 1: SEM with Manifest Variables

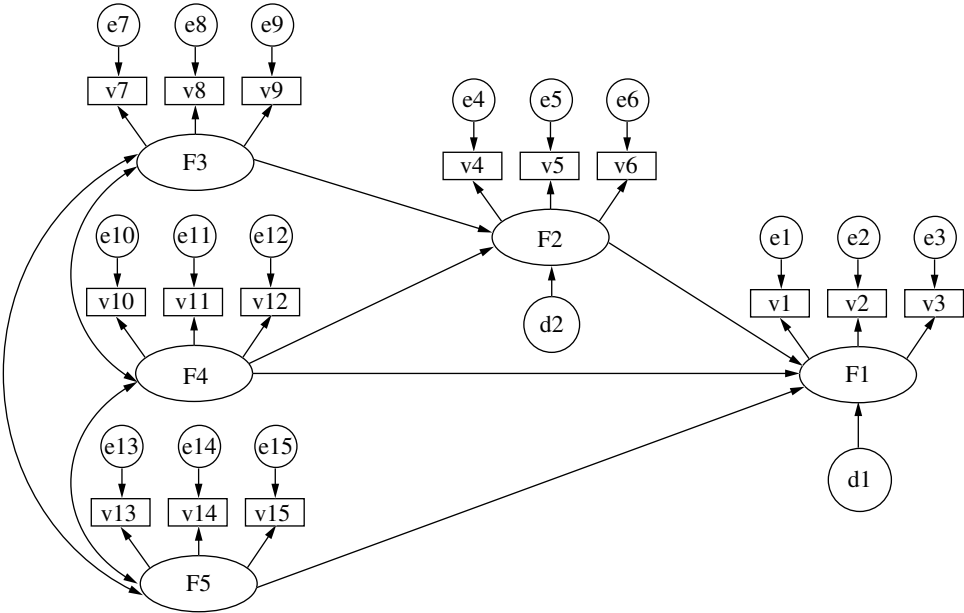
The theoretical model shown in Figure 1, technically considered a *path analysis with manifest variables*, suggests that three measured variables (v2, v4, and v5) have a direct causal effect on the variability of v1, which is the measured outcome variable of interest. The outcome variable v1 may be, for example, job performance, relationship satisfaction, or amount of credit card debt; the other variables may be trait and individual difference variables, such as conscientiousness (see Conscientiousness) and self-efficacy (see Self-efficacy), thought to have a bearing on the outcome variable. As indicated in the model, the three exogenous variables (v3, v4, and v5) are expected to correlate with one another. However, the model suggests that v3 is not hypothesized to have a direct influence on v1, as there is no path directly from the former to the latter. Rather, the model suggests that v3 has an *indirect* effect on v1; specifically, v3 influences v1 by first influencing v2. In other words, v2 mediates the effect of v3 on v1. The model further suggests that v4 has both a direct and indirect effect on v1. A path goes directly from v4 to v1, indicating a hypothesized direct effect.
Figure 1   Theoretical model with manifest.


Figure 2   Theoretical models with latent variables.

However, a path also goes from v4 to v2, and a second path goes from v2 to v1, thereby indicating that v4 also indirectly influences v1. The final components in this model, represented by e1 and e2, are error terms, which represent the effects of other sources of variability in endogenous variables, as well as measurement error in both variables.

Case 2: SEM with Latent Variables

The theoretical model displayed in Figure 2 is a path diagram illustrating a theoretical model in which the main variables of interest are latent variables, or factors, identified as F1, F2, F3, F4, and F5. As before, F1 is hypothesized to be directly predicted by F2, F4, and

F5, and indirectly by F3 and F4. Also, F1 and F2 are thought to influenced by "disturbance terms" (i.e. d1 and d2), which, in the case of path analysis with latent variables, have the same interpretation as error terms for manifest variables.

Because each of the five main variables is latent, they must be measured by multiple observed "indicator" variables. For example, if F3 represents self-efficacy, the arrows in the diagram indicate that this latent factor is expected to influence three manifest variables tapping into this construct, labeled here as v7, v8, and v9 (which might be, for example, three independent measures assessing self-efficacy). In SEM models with latent variables, the degree to which indicator variables measure a latent construct is assessed through *confirmatory factor analysis* (CFA). Unlike exploratory factor analysis (see Factor Analysis in Personality Research), CFA is hypothesis-driven in that the researcher must have a strong a priori sense of which indicators reflect a specific factor (Brown, 2006). The portion of SEM models that describe these relationships is called the *measurement model.* In CFA, the path coefficients extending from a latent factor to its respective indicators are factor loadings; if these loadings are large, it is reasonable to conclude that the manifest indicators are adequately measuring the latent construct. The portion of the model that assesses the hypothesized causal relationships between the latent constructs is called the *structural model.* In the figure, the structural model consists of the paths connecting F1, F2, F3, F4, and F5.

Case 3: SEM with Both Effect and Cause Indicators

The model displayed in Figure 3 is a particular kind of SEM model known as a multiple-indicator multiple-cause (MIMIC) model. A MIMIC model is a measurement model specifying one or more latent variables with one or more manifest exogenous causal predictors (Schumacker & Lomax, 2016). The model in the figure specifies that a latent variable (F) measured by three observed effect indicator variables (y1, y2, and y3), each having separate error terms, can be predicted by three observed exogenous variables (x1, x2, and x3), known in this context as "cause indicators" (Kline, 2005). Such a model may be useful, for example, if a researcher hypothesizes that emotional well-being (a latent individual difference variable having multiple hypothesized effect indicators) is influenced by several cause indicators, such as income, education, and marital status.

Acculturation Considerations in Personality Assessment

Ingrid K. Weigold[1] and Arne Weigold[2]

[1] *The University of Akron*
[2] *Kent State University at Geauga*

Acculturation refers to the process of acquiring a new culture. Often discussed in terms of the experiences of immigrants (including sojourners and refugees) and Native Americans, acculturation encompasses various ways in which individuals may assume aspects of a host or dominant culture, including language, behaviors, values, and attitudes. Traditionally, acculturation has been assessed unidimensionally, with one end representing complete assimilation into the new culture and the other indicating full adherence to the home culture. Current research splits this continuum into two constructs: acculturation and enculturation. According to the current understanding, acculturation measures the level of adherence to aspects of the host or dominant culture, and enculturation assesses retention of aspects of the home culture. Individuals may be at any level on either of the two continua, including high in both acculturation and enculturation, low in both, or high in one and low in the other (see Berry, 1997). For the purposes of this discussion, the construct of acculturation (rather than both acculturation and enculturation) will be emphasized.

Many of the personality assessments currently in use have an inherent bias that assumes test-takers ascribe to White North American or Western European cultural backgrounds. However, many test-takers do not come from such backgrounds or adhere to these worldviews. Level of acculturation has been shown to affect test scores on popular personality assessments, such as the MMPI, the Rorschach Inkblot Test, and measures of the Five Factor Model of personality (see Dana, 1996; Okazaki, Okazaki, & Sue, 2009). Consequently, several considerations must be taken into account in test development, administration, and interpretation to increase the validity of responses for test-takers with varied levels of acculturation.

Test Construction

The acculturation of test-takers relates to the test construction process in different ways. One of the most prominent is language proficiency. Use of the dominant language of a host country is both considered an aspect of acculturation (see Berry, 1997) and has occasionally

served as a stand-in for acculturation in research. At the most basic level, test-takers should be comfortable reading written assessments and understanding verbal instructions in the language in which the assessment is administered. Beyond this, it is necessary for test items to show cultural equivalence. Even if a word or phrase can be read by a test-taker, he or she may not necessarily interpret it in the way it was originally intended due to the word or phrase having different meanings in the languages of the host and home countries. Consequently, it is essential that test construction includes careful consideration of the language proficiency of the intended test-takers, including appropriate translation and adaptation of measures as necessary, to increase equivalence and reduce potential construct, method, and item biases (van de Vijver & Tanzer, 2004).

Another consideration of test construction is the effect of acculturation level on response choice. Different methods of responding to items have been shown to be affected by acculturation. For example, free-response options may lead to answers that are misinterpreted by the test administrator due to subtle differences in language (see van de Vijver & Tanzer, 2004). Alternatively, Likert scales and dichotomous choices, which are two of the most common item response formats, have been shown to be influenced by acculturation levels. For example, aspects of acculturation, including language proficiency, individual collectivism, and cultural values, have been shown to influence the tendency of Hispanic test-takers to respond with extreme or acquiescent scores and Asian test-takers to select midpoint options such that less acculturated test-takers within the United States had these types of patterns, whereas those that were more highly acculturated showed them to a lesser extent (Marín, Gambia, & Marín, 1992; see Wang, Hempton, Dugan, & Komives, 2008). Overall, research has shown that response tendencies fluctuate across countries and regions (Harzing, 2006). Therefore, it is important for test developers to consider response options when designing tests for use with test-takers who have varied levels of acculturation.

A final consideration is the standardization of measures and their normative groups. Although many modern personality assessments provide normative data that consist of diverse groups, few include analyses related to specific cross-cultural groups or account for potential within-group differences (Okazaki et al., 2009). Without such analyses, it is difficult to determine the potential impact that changes in language proficiency or the adaptation of different cultural values may have for specific groups. These may be especially important for instruments with set cut-off scores, such as the MMPI-2, as clinical decisions are often made based on their outcomes.

Test Administration

Level of acculturation has been shown to affect how test-takers respond to different aspects of personality test administration. The traditional North American model of test administration is typically impersonal and task-oriented, with an expectation that the assessment will be completed in a timely manner. Often, those administering the test only meet with the test-takers for the purpose of the assessment. However, many individuals do not prefer this style of interaction and might expect it to be different. When this occurs, test-takers can become uncomfortable with the testing process, which may affect their self-disclosure and responses to test materials. It is important for test administrators to be culturally competent and

understand the potential differences in personal style that may be necessary to elicit accurate responses, even with the use of cross-culturally validated instruments (Dana, 1996).

Other aspects of test administration affected by acculturation include the physical environment and the actual method by which the test-taker completes the assessment (van de Vijver & Tanzer, 2004). For example, the presence of other test-takers and their distance from each other may influence a person's comfort due to cultural differences in personal space preference. Additionally, modern methods of data collection, such as computers and the Internet, are not familiar to some test-takers, which may affect their responses. Therefore, it is essential for test administrators to be familiar with the potentially subtle effects of the environment on participants with various levels of acculturation.

Finally, language proficiency can impact a test-taker's understanding of the instructions for the assessment (van de Vijver & Tanzer, 2004). It is important for the test administrator to be familiar with the assessment, able to answer questions (and predict when it is likely that test-takers will not ask their questions), and provide clear and direct instructions. Failure to do so may hinder the ability of test-takers to correctly complete the test.

Test Interpretation

In addition to test development and administration, the accurate interpretation of test responses can be affected by the acculturation of the test-taker (van de Vijver & Phalet, 2004). The aforementioned acculturation considerations can impact a test-taker's responses, thus rendering his or her results invalid. If the test interpreter is not aware of these potential issues, the results can be inaccurately interpreted. Relatedly, the test interpreter may determine the results based on the dominant culture, without taking into consideration potential acculturation issues. This can lead to the overpathologizing of test-takers with lower levels of acculturation. For example, research has found that Asians who are less acculturated in the United States have higher scores on several of the MMPI-2 scales than both Asians who are more highly acculturated and non-Hispanic Whites (see Okazaki et al., 2008). Without an understanding of level of acculturation, erroneous clinical recommendations may be made.

Feedback to test-takers can also be influenced by aspects of acculturation (Dana, 1996). Similar to the test administration considerations, it is necessary for those providing feedback to do so with respect to cultural considerations, such as beliefs about mental health and the role of family members or others in the decision-making process. For instance, some test-takers will expect family members to make the ultimate decisions regarding any recommendations.

Recommendations for the Consideration of Acculturation

Researchers have posited several recommendations for considering acculturation in personality assessment. The first is to use tests that have cross-cultural validity and, ideally, have been examined for within-group differences of a specific population (Dana, 1996). A number of personality assessments have demonstrated at least some aspects of

cross-cultural validity, such as the Holtzman Inkblot Test and the Tell-Me-A-Story. This might include giving assessments in the first language of the test-taker, even when he or she is fluent in the dominant language. For instance, research has found that Hispanics in the United States may be more likely to respond with lower levels of culturally stereotypical responses when assessments are given in their first language.

A second recommendation is to assess for the acculturation of the test-taker (van de Vijver & Phalet, 2004). This can be done using validated acculturation measures and/or detailed information about the background of the test-taker, such as length of time in the United States. Based on the results, appropriate tests can be selected and their results interpreted in relation to the acculturation of the test-taker. Additionally, when assessments are given at multiple time intervals or are compared to previously administered tests, the results of acculturation measures may alert the test administrator that assessment responses may be due to changes in response tendencies or cultural understanding.

A final recommendation is that those developing, administrating, and interpreting tests are culturally competent (Dana, 1996). This is an important component in recognizing when personality assessments, which are often considered to be culture-free, actually contain bias or take an emic approach to culture. It also allows for the administration and interpretation of assessments in ways that take into account a test-taker's preferred culture.

Computer Adaptive Testing (CAT)

Hannah Masoner[1] and Amanda ElBassiouny[2]

[1] *Spring Hill College*
[2] *California Lutheran University*

Computer adaptive testing is a form of electronic testing that adjusts to the skill and knowledge level of the test-taker. These tests can be programmed to detect and grade the participant on their level of knowledge, preparedness, or mental status, depending on the purpose of the test. It can do this without spending extra time on unnecessary questions or on questions that are too difficult or too easy for the participant.

History

Alfred Binet, a French psychologist, was the first to utilize adaptive testing. In 1905, he tailored intelligence tests to focus on the individual person and their unique abilities rather than meeting the needs of a bigger group. He used a basic method of either increasing or decreasing question difficulty based on the way in which participants performed on the previous question. He was not concerned with making the test uniform, but rather tailoring the test to measure unique skills of the person he was testing. His method was efficient for individual use but not feasible for testing large groups. In the 1950s, Frederic Lord, a psychometrician for the Educational Testing Service, developed a modified, adaptive testing method called Flexilevel that could be used on large groups at a time (Linacre, 2000). This method employed an algorithm that allowed a test to rearrange the order in which the items were presented based on a fit between how difficult the item was and how the test-taker was performing. While test-taker may answer different items from each other on any given test based on how they are performing, the way in which the test is scored allows for the scores of all test-takers to be on the same scale and thus, comparable to each other. Additionally, the simple algorithm created by Lord also allowed for the tests to be self-scored.

Procedure and Methodology

The first step to any kind of adaptive testing is to formulate an item bank. This is a collection of questions, typically multiple choice, that are categorized by a ranking method called item response theory that distinguishes items by subject and level of difficulty. The ranking process is completed prior to the administration of the test. The test taking process is based on an algorithm that begins with a medium-level question based on the projected ability of the test-taker. If the participant answers correctly, they will then be given a more difficult question, but if they answer incorrectly, they are given an easier question. This process continues until the appropriate level of question difficulty is found, which is when there is a 50% chance that the test-taker could answer the question either incorrectly or correctly. If a question is too easy then there is a higher chance that it will be answered correctly, if the question is too difficult, there is a higher chance it will be answered incorrectly (Linacre, 2000). The test will continue to administer items until they are neither too easy nor too difficult. The test will continue until the programmed "stopping rules" are achieved. Test programmers will dictate these criteria depending on the purpose of the test. However, some general stopping points are when the item bank has been used to its capacity, the maximum test length has been reached, the person's level can be measured with precision, or when testing behaviors such as guessing or cheating are detected. While calculating answers, the computer is able to consider the possibilities of unlucky answers, mistakes, carelessness, and guessing by measuring the time it takes a person to answer the question or the pattern of what kinds of questions were missed. There are also certain criteria that must be met before the test can end. For instance, the minimum number of questions must be given, all topics or sections of the test must be covered, and sufficient answers in order to maintain validity of the final score must be administered (Linacre, 2000).

Advantages and Disadvantages

Computer adaptive testing's main advantages include efficiency, the ability to avoid asking questions that are irrelevant, and allowing the test to be more accurate. Owing to this, tests can be shorter and take less time. The computer is able to give immediate feedback once the last question has been administered and the scores are calculated. The ability of these tests to detect mistakes and irrelevant answers decreases the negative impact an item's mislabeled difficulty level can have on a student's score. These tests also increase security because they are administered electronically, as well as causing less fatigue for the participant being tested and the grader because it is all scored by the computer. Scores are based on the specific participant but can cover a wide range of abilities and skill sets. Overall, these give a better testing experience for both participants and administrators.

A major disadvantage with computer adaptive testing is that students cannot review past items on these types of tests because once the question is answered it is not shown again. This can cause problems if the test is being used for learning purposes. Additionally, it can also lead to misuse by the test-taker because a well-trained participant may try to answer the first set of questions incorrectly in order to receive easier questions on the remaining portions. In doing this, they are attempting to outsmart the test and receive a better score.

Another disadvantage is that people of the same skill level often have the same questions and could potentially share them with others. A way to avoid this would be to have completely randomized tests, but then the test becomes less efficient. Items on the test cannot be edited with ease because they must be tested ahead of time in order to categorize their difficulty correctly. Lastly, a major downfall to these tests is the funds that are required because administrators must purchase the programs to run the test, as well as the computers to administer them. This limits the places that are able to facilitate these tests.

Today's Applications

Today, computer adaptive testing is used in various ways by organizations, schools, research labs, and military branches. Many companies use computer adaptive testing for employee applications. These tests can help them determine if prospective employees have the qualities or skills required to excel at the position. Schools and educational programs use computer adaptive testing for entrance exams, such as the Graduate Management Admission Test (GMAT), the Graduate Record Examination (GRE), Test of English as a Foreign Language (TOEFL), as well as for cognitive assessments, such as the Woodcock Johnson intelligence assessments. Psychology research uses these tests to assess issues such as suicidal behavior and tendencies. For example, research performed by De Beurs, De Vries, De Groot, De Keijser, and Kerkhof (2014) applied computer adaptive testing to the Dutch version of the Beck Scale for Suicide Ideation (BSS) and showed that adaptive testing can reduce the length of this scale while more efficiently predicting suicidal behavior online. Military branches also use computer adaptive testing for the Armed Services Vocational Aptitude Battery (ASVAB), which allows them to estimate the success of incoming military applicants. Computer adaptive testing has also been used to evaluate the readiness of postwar soldiers and those dealing with post-traumatic stress disorder to be reintegrated into society. Computer adaptive testing is being used more frequently as researchers find new ways to utilize it. It is progressively becoming more common for measuring psychological phenomena, such as level and tendency toward depression as well as level of quality of life, especially in chronically ill patients.

Culture-Free/Fair Intelligence Testing

Evan J. Anderson and Femina P. Varghese

University of Central Arkansas

Defined

Creating a construct that summarizes an organism's (and recently machines) ability to think, communicate, learn, plan, and solve problems has been an important goal of science for many years. By continuation, so has the measurement of this construct. One of the first attempts at measuring and operationalizing the concept of intelligence was made by Sir Francis Galton using comparatively primitive instruments to measure an individual's reaction time as an indicator of cognitive ability. Since this humble beginning, the theories of intelligence have expanded to include, among other things, verbal and non-verbal reasoning, memory, and processing speed. As the understanding of intelligence expands, so too must our measurement strategies.

Recently, intelligence researchers have extended their gaze to study intelligence conceptualizations from other countries and cultures to see how they differed and/or agreed with the Western ideas of intelligence. Not surprisingly, there were some fundamental differences. For instance, E. A. Cocodia (2014) in his work *Cultural Perceptions of Human Intelligence* reported that while there were many similarities between Asian, Western, and African notions about intelligence, they also differed in many ways. While Asian and Western cultures emphasize formal, academic learning, African cultures tended to emphasize social savvy and practical skills. Additionally, Western cultures appear to be unique in the desire to conduct a task quickly. Asian cultures uniquely incorporate religious values into their views of intelligence and place more emphasis on self-improvement.

Since almost all intelligence assessments are based on Western constructs of intelligence, it is important to consider how researchers can measure intelligence across cultures. One of the answers to this question is to use intelligence assessments that attempt to control for cultural factors called culture-free or fair intelligence assessments.

Culture-Free Intelligence Tests

Richard Arvey in his comments on culture-free tests reports that culturally fair tests were first developed out of the desire to assess the abilities of non-English speaking immigrants just preceding World War I. Knowing that using verbal reasoning tasks would be unreasonably challenging, the United States emphasized non-verbal tasks to assess aptitude. Subsequent to this, culturally fair tests were frequently used in the U.S. Army to assess aptitude in new recruits. Arvey also notes that it was not until 1951 when the book *Intelligence and Cultural Differences* was published that society started to realize that individuals within a culture could be tested unfairly based on variables such as socio-economic status. From this point, culturally fair tests became more widely used and studied.

Culturally fair IQ testing is controversial with Anne Anastasi stating that by definition such tests control factors that are relevant in predicting outcomes such as success in work, not just test scores. Anastasi (1997) indicates that using non-verbal content instead of verbal might influence the score, but might influence its predictive validity in a context that requires verbal ability. Arvey suggests dimensions that may negatively affect overall test performances as the written format, heavy on verbal tasks, focus on speed, instructions that need to be read by the test-taker, and using items that may be unfamiliar to certain groups. Tests that focus on performance tasks, non-verbal reasoning, instructions that are read to the person, and content items that are more universally familiar to individuals are more likely to yield more consistent results across cultural and subcultural groups.

However, this theory is not perfect and has been shown to vary with many variables. A meta-analysis conducted by De Vijver (1997) found key areas that affected performance on cognitive tests. First, scores become more separated as affluence, and chronological age increase, meaning that culturally fair assessments have limits to the number of cultural variables they can account for. This analysis supports conclusions made by Arvey (1972). However, De Vijver's meta-analysis suggests that ethnic differences in cognitive task do exist, but suggests this may be influenced by of a variety of factors such as familiarity with the subject matter. So while there is some evidence that culturally fair IQ assessments have limitations, most evidence supports the choice to use such assessments.

When dealing with cultures that have different languages, values, and beliefs, it is easy to see how assessments that emphasize pictographic and other nonverbal reasoning tasks have more concurrent results than an IQ test that has been standardized on a Western population and includes verbal reasoning skills as a requirement. If items on an IQ assessment are too unfamiliar, then it becomes difficult for individuals to demonstrate their reasoning ability (Kline, 1991) and comparing those groups based on those scores would tell us little. However, even the non-verbal items are not completely unbiased. For example, Benson (2003) shares statements from Dr. Patricia Greenfield who states that most of the culturally fair tests utilize matrix reasoning tasks that strongly favor individuals with formal education since formal education often teaches pupils to work in lines and columns.

Further, according to Dr. Greenfield, as indicated by Benton (2003), individuals who come from cultures that consume written media may have the advantage in verbal reasoning. While on the topic, many authors and researchers contributing to this realm of work acknowledge the need to make some comparisons across cultures but warn against mindlessly comparing groups with the same test as this can begin to establish an unnecessary hierarchy.

Future of Culturally Fair Assessment

According to Serpell (2000) using more performance-based measures can help a test to be more culturally fair; there are other variables that need to be accounted for that exist outside of the actual test. Many researchers feel the future of culturally fair testing lies in two primary areas.

Benson's (2003) article suggests an important step in developing culturally fair testing is to continue to refine the tests and shift from the idea that we need one test to assess everyone and start to move toward tests created for singular groups or cultures that focus on their values and needs. In other words, researchers need to cease trying to identify individuals who are the most intelligent by Western standards and focus on identifying who is most intelligent by their culture's standards. In the past, many researchers felt that translating tests used in Western intellectual assessments would be adequate to assess accurately everyone's IQ. Now, researchers say otherwise citing that culture goes well beyond language and needs to consider traditions, attitudes, and societal norms (see Benson, 2003). However, it may not be entirely necessary to build a new test from scratch. Researchers Ashley Maynard and Patricia Greenfield and Carla Childs (2015) were able to measure successfully cognitive development in a Zinacantec Mayan village in Mexico by using objects and situations familiar to the Zinacantec. Additionally, research conducted by Shaunessy, Karnes, and Cobb (2004) found that standardized culturally fair tests become more effective if combined with multiple culturally fair tests since different tests focus on different cognitive abilities.

The second area of improvement does not deal with the form of the test but rather the administration. Many of the negative issues surrounding culturally fair testing occur during the administration and can address if the examiner is aware of them beforehand. Fletcher-Janzen and Ortiz (2006) suggest ways to reduce the effect cultural differences can have on an individual's performance. Fletcher-Janzen and Ortiz (2006) state that the first is to develop a sense of self-awareness. Acknowledge that often the most biased part of the assessment is the evaluator (Fletcher-Janzen & Ortiz, 2006). Recognize that the examinee may have different values and beliefs from your own (Fletcher-Janzen & Ortiz, 2006). According to Vernon (1979), much of the time individuals come from a background that places little emphasis on formal education. Fletcher-Janzen and Ortiz (2006) state that accessors need to remember, what intelligence looks like to them is not necessarily what it looks like to the subject. Second, establish rapport with your client. Many clients who are from a minority culture will be anxious about the testing and maybe even distrustful of the examiner (Fletcher-Janzen & Ortiz, 2006).

Fletcher-Janzen and Ortiz (2006) recommend ways that researchers and administrators can improve cross-cultural testing when applying intelligence assessments for practical purposes such as the identification of special needs or gifted populations. First, assessors need to take part in establishing criteria for identifying children who are worthy of being tested for access to special services. Since many children from diverse cultures do not fit into the classic mold of Western intelligence, it is important to educate schools and administration on the many forms intelligence can take. Next, administrators of tests should choose how they evaluate the culturally diverse carefully. In addition to using appropriate standardized measures, examiners should consider using alternative forms of assignments

such as videos or more visual presentations instead of written assignments to try to identify talents that may have otherwise gone undiscovered. Lastly, all the previously mentioned information should be considered while interpreting the assessment results and the child's culture and environment should be considered.

Item Analysis

Dong Xie and Cory L. Cobb

University of Central Arkansas

Conceptualizations

Item analysis is one of the essential steps in scale construction of personality assessment. It broadly refers to the procedures of evaluating the characteristics of items and their psychometric properties in measuring a personality construct. The purpose of item analysis is to identify items to be retained, revised, or removed from the item pool, so as to improve the overall psychometric quality of the instrument. In personality assessment, item analysis is most used in development of self-report personality inventories, or objective personality tests, rather than projective techniques.

The purpose of assessment is to make inferences about the level of the trait it intends to measure based on examinees' responses, often summarized as scores on the assessment. An assessment consists of items and the item quality depends on the extent to which the items can provide information to make such inferences. A good assessment should only contain items that provide high levels of information concerning the trait, which is determined by two important indexes: item discrimination and item difficulty.

Item Discrimination

Item discrimination regards how well an item can distinguish between individuals having different levels of the trait the assessment intends to measure. An item is discriminative if individuals with different levels of the trait endorse different response categories on the item. Two formats of response categories most often used in personality assessment are the dichotomous format and the polytomous format. For dichotomous items, there are only two response categories, such as "*Yes*" or "*No,*" "*Like*" or "*Dislike,*" "*True*" or "*False.*" Polytomous items have more than two response categories and are often in the form of Likert-type rating scales. An item would provide little information in differentiating the individuals with different levels of the traits if all of them endorse the same or similar categories.

Item Difficulty

Item difficulty may be easier understood in tests of abilities, skills, and knowledge where evaluation of such traits depends on an examinee's *correct* responses to items. In this situation, the term *difficulty* makes more sense as it can be defined as the percentage of examinees who answer the item correctly. The item is difficult when fewer people answer it correctly and is easy when more people answer it correctly.

In personality assessment, personality traits are evaluated without correct answers. Indeed, many personality instruments often remind participants that there are *no* right or wrong answers while providing instruction during administration of the assessment. However, item difficulty is still an important index of item quality in personality assessment and can be understood as the portion of the trait continuum for which the item provides information. Psychological traits operate on a continuum with a range varying from low, moderate, to high. An item can differentiate individuals with relatively high levels of trait but not those with relatively low levels of the trait. In this situation, respondents with high levels of traits will choose different response categories while those with low levels of traits will endorse the same category.

Approaches to Item Analysis

Item analysis often involves two general approaches: qualitative and quantitative. The qualitative approach relies on the reviewer's judgment concerning the general qualities of the item: appropriateness of item content and format in accordance with the purpose of the assessment and intended population, clarity of grammar and expression, and item reading level. The reviewers are often experts in the subject matter related to the trait the assessment intends to measure. Possible sources of bias or languages offensive to a specific subgroup of the population can be identified, modified, or eliminated.

In most self-report personality assessments, item analysis is quantitative in nature and involves use of various statistical procedures to assess item discrimination and difficulty. The quantitative methods can be further classified based on two theoretical foundations: classical test theory (CTT) and item response theory (IRT).

CTT-Based Item Analysis

CTT has been widely used for decades and will continue to be the dominant theory in guiding scale development in personality assessment. The theory focuses on the total score of an assessment which is the sum of individual item scores. According to CTT, the information contained in this observed summated score comes from two sources: the actual level (or true score) of the trait and the error during the process of assessment. Therefore, the CTT approach to item analysis is to evaluate item discrimination and item difficulty so a to ensure that an item can provide the most information concerning the true level of the trait while creating minimal error in the assessment.

Under CTT, item discrimination is evaluated through item-total correlation. Because CTT assumes the total score as an approximate estimate of the true level of the trait, an item would contain high levels of information on the trait if it is highly correlated with the total score. Item-total correlation is often used in combination with analysis of internal consistency

reliability (i.e. Cronbach's alpha) by comparing the alpha coefficients. If an item has a low item-total correlation and the alpha coefficient increases when this item is removed from calculation, then it would be flagged for revision or removal from the item pool.

With CTT, item difficulty is evaluated through the mean of the responses to an item. In tests of ability where correct answers are involved, the lower the mean, the more difficult the item. In such tests, an extremely difficult item will provide little information because most of the intended sample would fail to respond correctly to this item. Similarly in personality assessment, the mean of the responses to an item represents the range of the traits within which the item will provide information. Therefore, the purpose of examining item difficulty is to identify the items that have a particularly extreme level of means for the responses. These items then can be flagged for modification or removal because they may only provide information for levels of the trait that are more extreme than most of those observed in the intended sample. In most cases of personality assessment, an instrument is often developed to measure traits at all levels. Therefore, it is important for the instrument to have items with a range of low, moderate, and high difficulty.

IRT-Based Item Analysis

IRT refers to a wide range of mathematical models that are relatively new but have been increasingly used in test construction. Unlike CTT's focus on the total score of an assessment, IRT approaches focus on the relationship between a response to an item and the probability of such a response in tapping into the latent trait that the assessment intends to measure. IRT assumes that the response an individual may give to an item is a function of the level of his or her latent trait. Therefore, item analysis under IRT focuses on fitting a mathematical function that characterizes the relationship between the item response and individual differences on the latent trait. Each item has its own characteristics or functions in relation to the latent traits and such characteristics or functions are displayed through item characteristic curve (ICC). The goal of IRT-based item analysis is to find a model such that the estimated ICC best represents or fits the observed item response data.

IRT-based item analysis often involves evaluation on two types of parameters, *a* parameter, and a set of *b* parameters, representing item discrimination and item difficulty, respectively. The *a* parameter, also known as the discrimination parameter, is an estimate of item discrimination, which determines the steepness of the ICC. The greater the *a* parameter, the steeper the ICC, and the greater the item discrimination. The *b* parameters are estimates of item difficulty of transitioning from one level of a trait to a higher level of a trait. Therefore, the *b* parameters, commonly referred to as location or transition parameters, determine the location of the ICCs along the latent trait continuum. It is beyond the scope of this entry to explain in detail the calculation and interpretation of these parameters, but readers can read a chapter by Randall Penfield (2013) on item analysis for procedures and examples in IRT-based item analysis.

CTT and IRT approaches to item analysis each have their own advantages. CTT has the advantage of having simple procedures and requires relatively small sample sizes for adequate estimates of item discrimination and item difficulty. IRT has principles that are more theoretically and empirically justifiable and has a greater potential in solving practical problems in assessment, such as reducing the length of assessment. Under IRT, item sequence can be individually tailored to the test taker's latent trait levels based on prior

responses. This allows for a more flexible and efficient format of administering the assessment such as the computer adaptive testing (CAT).

Further Considerations and Strategies

Item analysis serves to flag suspected items for revision or removal from item pools based on item discrimination and item difficulty. However, the decision to retain or remove an item should not rely on these indexes only, but rather take into account other contextual factors such as the content domain of the trait, purpose of the assessment, its intended population, and practical constraints.

One important consideration is that removing an item may affect the validity of the assessment. Items should adequately represent the content domain of the trait intended for assessment. Removing an item may reduce the representation of a particular domain so the item may better be retained even though it may have less discrimination. Although high discrimination is desirable, having all or most of the items with very high discrimination does not necessarily ensure the quality of the assessment. When all or most of the items have very high item-total correlations, these items are highly inter-correlated and do not provide much more information than one single item. Such a high inter-item correlation may also suggest that the domain content of the trait has not been adequately sampled by these items. While having all the items highly inter-correlated will enhance the internal consistency reliability, it may compromise the validity of the assessment because these items may only represent a specific narrow range of the content domain. Therefore, it is important to evaluate to what extent these items have covered the range of the domain trait and if additional items are needed to cover other aspects of the trait.

Another strategy to ensure the validity of the assessment is to correlate item responses to some external criteria. While an item can be evaluated through its correlation with the assessment's internal criteria (i.e. the total score), similar procedures can be used with external criteria. An item having a high correlation with an external criterion, such as actual performance or observed behavior typical of the trait, will contribute to criterion validity of the assessment. Furthermore, factor analysis can be used to examine the item in regards to the construct validity of the assessment if the trait can be conceptualized as having a structure comprising some sub-traits. Evaluating the item's factor structure coefficient, commonly known as factor loadings, can reveal the extent to which the items are related to each other in a manner consistent with the intended structure.

Fairness is an important issue in assessment. The fairness of an item concerns whether its content is invariant across different demographic groups, or biased toward certain groups. For example, item familiarity can affect the fairness of an assessment. If an item is unfamiliar to a minority group, then examinees from this group may not respond to the item in the same manner as those who are familiar with the item, assuming they are at the same level of the trait intended for assessment. While the fairness issue of an item can be examined qualitatively through an expert's judgment, it can be empirically tested with differential item functioning (DIF) analysis. DIF analysis, an approach based on IRT, compares the ICC between the focal group and the reference group. Items with significantly different functioning across the groups are flagged for further revision or removal from item pool.

Reliability, Issues of

A. Nayena Blankson

Spelman College

Reliability Defined

Reliability is a measure of the consistency of a test. For example, a ruler to measure length yields the same measurement on repeated trials. It is consistent. Reliability is a necessary, but not sufficient condition for validity. If the ruler were used as a measure of weight instead, although the measurements would not be an accurate representation of weight (i.e. valid), the measurements would be consistent on repeated trials (i.e. reliable).

Early conceptualizations of reliability can be traced back to Charles Spearman (1904, 1907, 1910). Theoretically, a person's test score (X) is equal to the individual's true score (T) plus a random error score (E). This idea can be represented by the equation

$$X = T + E.$$

A true score is the average score that would obtain if an individual were administered a test an infinite number of times. The average error score over repeated testings is expected to be zero. The total variance of a test in a population of individuals is equal to the variance of the true scores plus the variance of the error scores. Hence, the reliability of a measure can be conceptualized as a ratio of the true score variance to the total variance (i.e. the variance in observed scores).

Because true scores and error scores are hypothetical, they cannot be directly observed. Therefore, the reliability of a test cannot be empirically derived; it must be estimated. Several different methods have been proposed for estimating reliability. These methods fall under for general categories, namely inter-scorer reliability, test-retest reliability, alternate forms reliability, and internal consistency reliability. All of these will be described, as well as generalizability theory.

Types of Reliability

Inter-scorer reliability is an estimate of reliability that can be calculated if the types of scores that are obtained from the test are observer ratings. There should be at least two different raters and it is best if the raters are blind to the ratings of one another. The calculation of inter-scorer reliability depends on the level of measurement for the ratings. If the ratings are on a nominal or ordinal level, then the percent agreement can be computed. A Pearson correlation can be computed when there are two raters and the ratings are on an interval or ratio scale. If there are more than two judges who rate using an interval or ratio scale of measurement, then an intraclass correlation can be computed.

Test-retest reliability is computed simply as a Pearson correlation between a measure that has been administered to the same sample of individuals at two different time points. Ideally, the time spread should be chosen to allow for full decay of memory for the responses given on the first testing, although this might not be possible practically. The most commonly used time span is a two-week interval. High test-retest reliability is evident when there is a strong positive correlation between the scores obtained from the two testings. Test-retest reliability assumes that the construct being measured by the test is a stable trait. There are attributes that may not to be stable over time (e.g. mood) and test-retest estimates would suggest low reliability for measures of these constructs. Carry-over or practice effects from one testing to the other may also cause the test-retest estimate of reliability to be incorrect or attenuated.

Parallel forms reliability are computed as the correlation between two parallel forms of a measure. Two tests are considered parallel if: (1) they measure one and only one common factor, (2) the original test and the alternate form have the same standard deviations, (3) the original test and the alternate form have the same correlations with a set of true scores, and (4) the variance in each test not explainable by true scores is due to random error. Tests may also be parallel in content. In the case of content-parallel tests, the item contents are equivalent across tests but not necessarily within a test. If items are parallel across tests, but are not parallel within a test, it can be found that a test has parallel forms reliability but has low to zero internal consistency reliability.

Estimates of reliability as internal consistency most often include the split-half reliability coefficient (Spearman, 1910), the Kuder-Richardson 20 coefficient (KR-20; Kuder & Richardson, 1937), and the coefficient alpha (Guttman, 1945; Cronbach, 1951). To obtain a split-half reliability coefficient, the test is administered to a sample of participants, and then split into equal halves and scored. There are several ways in which one can split a test in half, such as an odd-even split. If the variances of scores for the two half tests are equal, the split-half reliability coefficient may be computed by calculating a Pearson correlation between the two half-test scores. Because correlations are calculated between half tests instead of full-length tests, reliability will be underestimated. Therefore, the Spearman-Brown prophecy formula can be used to derive the reliability of the whole test, based on the half-test correlation coefficients.

If, on the other hand, the variances of the two half tests are not equal, the Kuder-Richardson-20 (KR-20) formula can be used to estimate reliability. In calculating this reliability coefficient, it is assumed that that all items measure the same factor (Kuder & Richardson, 1937). If the assumption of equal standard deviations is also made, the

resulting estimate is equal to what would obtain if a split-half reliability coefficient were computed (corrected for by the Spearman-Brown formula). The KR-20 estimate of reliability is applicable for items that are dichotomously scored. For multichotomous or quantitative items, the KR-20 is referred to as coefficient alpha. Cronbach (1951) showed that coefficient alpha is the average of all possible split-half coefficients (uncorrected for by the Spearman-Brown formula). Therefore, KR-20 and the split-half coefficient are particular cases of alpha.

The internal consistency coefficients of reliability discussed thus far make the assumption of a one common-factor model, but they do not provide a test of whether a set of items measures one and only one common factor reliably; rather, they are estimates of reliability that provide an index of the common-factor concentration among the items in a test – i.e. the extent to which the items measure "something" in common and this something could be multidimensional (Cronbach, 1951; McDonald, 1999). The coefficient omega, on the other hand, is an index representing the extent to which a set of items measures one and only one common factor. Omega is an internal consistency reliability coefficient based on the parameters of a single factor model. The factor loadings and unique variances can be obtained by fitting a single-factor structural equation model to the sample covariance matrix to compute omega.

The coefficient alpha has been described as a lower bound for omega (McDonald, 1999). However, it is not necessarily the case that in practice coefficient alpha will be found to be lower than omega. There are instances when coefficient alpha can be larger (when the items measure more than one common factor) than omega and instances when it may be smaller (e.g. when the items measure one common factor) than omega (Horn, 2005). McDonald showed that the value for alpha equals the value of omega, if and only if the factor loadings are the same for all the items in the measure.

Finally, under the classical measurement theory of reliability, error components are undifferentiated. Error, however, is not a unitary construct. There can be several sources of error in any measurement. Although this fact was acknowledged in earlier works (e.g. Spearman, 1904; Guttman, 1945), the estimates of reliability that are derivable under classical test theory do not allow an estimation of the possible different sources of error variance in a measure. An alternative conceptualization of reliability is reliability as generalizability, for which the estimates of reliability do take into account different sources of error variance.

In conclusion, since the time of Spearman, various concepts of, and methods for, assessing the reliability of a measure have been developed. In some instances, one estimate of reliability may be a more appropriate measure of reliability than another. Furthermore, use of one coefficient may indicate low to zero reliability of a test while another coefficient may indicate high reliability. For example, a measure can have high test-retest reliability and a low coefficient alpha or vice versa. For instance, a scale to measure mood may be shown to be reliable in that it is internally consistent and measures one and only one common factor (i.e. mood). The same test may be found to have low to zero reliability if the test-retest method is used, since mood is not a stable attribute. Each reliability coefficient has its own meaning and value. The meaning and value of each of the coefficients should be carefully considered in evaluating and describing a test.

Issues of Response Styles

Kathryn Bruzios and Elizabeth Harwood

Rivier University

Response Bias

Response bias occurs when factors outside of what the researcher intends to measure influence the respondent's answers to survey items. These factors increase the chance for error and data contamination leading to incorrect conclusions. Response bias may arise intentionally or unintentionally and is derived from a mixture of response styles and response sets. Response styles are related to the respondent's characteristics which lead the respondent to distort their approach to the given assessment procedure. Responding to items in a way that follows social norms instead of one's true opinion is an example of a response style. Response sets are response distortions that are related to the procedure, assessment, or situational circumstances. For example, having a survey that is too long can cause respondents to become tired of answering questions toward the end of the survey, resulting in less accurate responses. Response sets are temporary (e.g. reacting to the length of a survey at the end of a long day), while response styles are stable over time (e.g. a respondent's trait level of agreeableness). However, the definitions of response styles and response sets are inconsistent across the literature and are sometimes used interchangeably.

The Question-Answer Model

In *Thinking about Answers: The Application of Cognitive Processes to Survey Methodology,* Sudman, Bradburn, and Schwarz (1996) discuss the Question-Answer Model which illustrates the cognitive process of answering survey items and provides one reason why response styles and response sets occur. Respondents begin by interpreting the question at hand (i.e. reading and determining what they think the question is asking). They put their cognitive processes into gear when looking for information to form an answer (i.e. trying to recall a memory or decide on an opinion). Respondents create judgments about what to include to answer the question appropriately (i.e. how much detail to provide). Afterwards,

they edit the answer to fit the context (i.e. choosing the correct answer from close-ended response choices). Respondents' invested cognitive involvement can differ based on how much thought, time, and effort they are willing to put into this process. If their motivation and abilities are low and the question is difficult, the participant is more likely to satisfice or provide a "good enough" answer rather than an accurate answer (Engel & Köster, 2014).

Response Styles

Personality research is most concerned with four major response styles – extreme response styles, mid-point or mild responding, acquiescence, and social desirability (including faking and malingering), all of which can be exacerbated by satisficing (Engel & Köster, 2014; Helmes, Holden, & Ziegler, 2015; Paulhus & Vazire 2007). An extreme response style is the respondent's tendency to answer items using the extreme ends of a scale (e.g. strongly disagree or strongly agree). Rather than focusing on the extreme ends, mid-point responding is such that the respondent answers items using the mid-scale option (e.g. neutral, neither agree nor disagree), whereas mild responding is the tendency to avoid using scale extremes (e.g. agree, disagree).

Acquiescence occurs when the respondent is inclined to agree with survey items despite content and actual opinions (e.g. agree or strongly agree), whereas disacquiescence or reactant individuals choose to disagree despite content (e.g. disagree, strongly disagree). Acquiescent and disacquescient response styles are more likely to occur in two-choice scales (e.g. yes-no, true-false) or when the question is ambiguous or vague. Acquiescence varies most across cultures because of the different emphasis on the value of the trait agreeableness (Johnson, Kulesa, Ik Cho, & Shavitt, 2005); thus it is important to identify cultural norms when designing personality research.

Finally social desirability responding is of great concern to researchers as it can be caused by a multitude of factors. Social desirability responding is when the respondent tries to make themselves "look good." Current research has found that social desirability responding can be best explained by self-deception (e.g. respondents believe positive self-reports) and/or impression management (e.g. exaggeration, faking, or lying, in self-reports; Helmes et al., 2015). While self-deception is unintentional, in impression management, the respondent intentionally gives a false response. This can be either "faking good" which is giving the most positive response, or "faking bad" which is giving the most negative response, also known as malingering.

Response Sets

Response sets are the result of external dispositions, such as issues with the construction of the survey or the setting in which the survey takes place. There are two main concerns with survey construction – response order and question wording.

The presentation of response options, known as response order, may influence the way in which respondents answer questions. For example, if questions are presented to participants on show cards, primacy effects can occur because items presented earlier have deeper cognitive processing (Krosnick & Alwin, 1987). This can also cause satisficing because if participants are

offered a large amount of responses, they may choose an answer that is just satisfactory. On the other hand, when questions are read orally, participants have less time to process all of the response options, thus leading them to choose the most recent option they heard, known as the recency effect (Krosnick & Alwin, 1987). When participants are given surveys, they have the autonomy to decide which questions they answer first; thus the measures that are completed at the beginning will probably have been given more thought than the ones completed at the end.

Bradburn, Sudman, and Wansink's (2004) book, *Asking Questions,* identifies several concerns with question wording including loaded questions, leading questions, and offensive language. Loaded questions contain biased wording of a controversial question. For example, "*Do you find your financial aid package to be fair?*" is not considered loaded, while "*Do you feel cheated due to your financial aid package?*" implies that something negative is occurring. Leading questions use wording and phrases to sway a participant to a desired response to support the researcher's position. For example, "*Did the man with the brown hair hit you?*" suggests a man with brown hair is the culprit, whereas "*Who hit you?*" is open for the respondent's interpretation. Double-barreled questions include more than one topic in a question, but only allow for one answer. "*Do you enjoy the summer and going to the beach?*" incorporates two questions into one. Additionally, using offensive language may bias certain socio-economic or cultural populations' responses, while complex wording may cause participants to use satisficing.

Other potential concerns with response sets include the setting of the data collection (i.e. taking a survey in a loud room), interviewer/data collector's experience (i.e. having a data collector who is not able to answer participants' questions or alleviate concerns), or length of the study (i.e. extensive questionnaires or timely interviews).

Distinctions between Response Styles and Response Sets

Response sets may be interrelated with response styles, making the distinction between the two unclear. For example, taking a personality measurement for a new job could increase social desirability bias, thus both setting and personal characteristics are at play. Extreme responding could be related to an individual's personal characteristics or it could be related to an individual's frustration from a long assessment which leads to satisficing. Kieruj and Moors (2013) examined this distinction and found that extreme responding occurred regardless of the response scale's length. Extreme responding was linked with multiple personality factors such as extraversion, intelligence, strongly opinionated, etc. The study concluded that the extreme response style is a *response style* and not a *response set*. More research is needed to understand the distinctions between response styles and response sets.

Controlling for Issues of Response Styles and Response Sets

Research has identified several ways to control for issues of response styles and response sets to help elicit more accurate conclusions (Paulhus & Vazier, 2007). Determining how a study is going to control for response styles and sets *before* collection takes place is important, because the least effective way is to control for it later. One method of control is

ensuring participants' anonymity, which can reduce social desirability and other response styles. While administering a test, rushing through the instructions, emotional arousal, and distractions should be minimized to reduce stress. Other methods are related to the test construction process. For example, when writing questionnaires, items should be clear and unambiguous. The questionnaire should also be concise, so the respondent does not get tired of answering the questions and satisfices.

To control for extreme responding, a dichotomous scale may be used (Paulhus & Vazier, 2007), although this can increase the chance of acquiescence. There are no standardized instruments for assessing extreme responding. Furthermore, acquiescence may result in inflated correlations (Paulhus & Vazier, 2007). To prevent this, reverse scoring can be used, with some items having the higher rating equaling possession of a trait and some items having the lower rating equaling possession of a trait. Thus, the respondent must agree with some and disagree with others to receive a high score in the trait the survey is measuring. If they agree with the question, "*I enjoy most outdoor activities*" then they should disagree with the question, "*I prefer to spend my time indoors.*"

Direct approaches to reducing social desirability would be to emphasize confidentiality, build rapport with the participant, and appear non-judgmental. Answers may also be forced choice, with a dichotomous scale in which both responses are considered socially desirable. An example is "*Would you prefer a partner that is a) active or b) intelligent?*" Using scales such as a lie scale or scale measuring social desirability responding can further assess the validity of the respondent's answers (Paulhus & Vazier, 2007).

Most personality batteries include validity subscales that help researchers catch response style issues. Helmes and colleagues (2015) review nine commonly used impression management and response bias scales, including the Minnesota Multiphasic Personality Inventory's (MMPI) revised edition which includes several measures to detect distorted response styles. The Eysenck Personality Questionnaire also includes a lie scale that accounts for a third of the questions to be forced in a positive direction. This aims at detecting "faking good." *Measures of Personality and Social Psychological Constructs* (2014) goes beyond issues of personality assessment and includes specific measurements such as those of emotion regulation and interpersonal styles, which could affect the validity of results (Boyle, Saklofske, & Matthews, 2014).

Responsibilities of Testing Professionals

Cristina L. Magalhães[1] and Lekeisha A. Sumner[2]

[1] *Alliant International University, Los Angeles*
[2] *University of California, Los Angeles*

Testing refers to the use of instruments and procedures to measure psychological phenomena that cannot be directly observed such as cognitive abilities, personality traits and emotional states. It helps professionals make inferences and predictions about a person's functioning, and is often used as part of a comprehensive assessment process to answer specific referral questions such as whether a candidate is a good fit for a job, or the nature and extent of a client's academic or mental health strengths and challenges. As such, testing can have a significant and oftentimes long-term impact in people's lives, and must be conducted responsibly to ensure the process will result in valid conclusions, appropriate decisions, and helpful recommendations.

Testing enhances the assessment process when conducted skillfully and responsibly but can be ineffective, or even detrimental to test takers, under conditions that compromise the process' integrity. Examples of these conditions are (1) when instruments are poorly constructed, or are used in inappropriate contexts or with unintended populations; (2) when users do not have sufficient training or experience with testing or have limited knowledge of the instruments they use; (3) when test takers are not well informed of the purpose of testing and the procedures involved, such that they are unable to provide informed consent or perform optimally during administration; or (4) when raw data, protocols, reports and other testing materials are inappropriately handled, disclosed without clients' consent, or made available to individuals who are not trained to interpret or use them effectively.

Concerned with the potential for misuse of tests, several professional organizations in education, counseling and psychology have developed guidelines for testing professionals to encourage responsible testing practices (e.g. the American Counseling Association, the American Educational Research Association, the American Psychological Association, and the National Council on Measurement in Education). Testing professionals are considered those who develop tests and other testing materials, such as test manuals and computer scoring systems (*test developers*); those who select and administer tests to clients, interpret data, and produce integrated reports (*test users*); and those who are trained to use

testing information to form impressions and make recommendations or decisions that will impact test takers (*information users*) (APA, n.d.). The following sections discuss the responsibilities of testing professionals in three main areas: professional qualifications; selection, administration and interpretation of tests; and handling of testing data. The following discussion applies primarily to test and information users. Readers seeking guidelines for test developers may refer to the *Handbook of Test Development* edited by Steven Downing and Thomas Haladyna.

Qualifications of Testing Professionals

Testing is a complex professional activity involving multiple tasks, each requiring specific knowledge and skills that take a significant amount of training and practice to develop and master. Different tasks may be performed by a single person or by different individuals working as a team. For example, one professional may be responsible for reviewing referral information and deciding which tests should be used, another for administering and scoring the tests, and another for interpreting the data and writing the report. Regardless, all professionals involved in the testing process are responsible for acquiring the competencies they need to perform their role. Some tasks may be performed by professionals with limited training and experience if supervised by a fully qualified testing professional (e.g. test administration and scoring).

Standard test user qualifications vary depending on the type of tests being used. For example, personality and intelligence assessment measures are often used as diagnostic tools in clinical or counseling psychology practice and typically require several years of graduate level training and experience to administer, score, and interpret. In contrast, rating scales designed to measure specific behaviors, such as smoking or exercising, can be aptly used by well-trained professionals with a Bachelor's degree to screen for cases that need follow-up by a specialist. Moreover, testing is performed by professionals from various disciplines, with different educational backgrounds and for different purposes (e.g. educators to make school placement decisions, vocational counselors to help inform clients' career choices, forensic psychologists to make recommendations regarding custody arrangements); thus, qualifications can also vary depending on the context or setting in which tests are used.

There are however general areas of competence all testing professionals must master regardless of field of expertise or areas of practice. For example, testing professionals must have knowledge of theories of measurement and test construction, understand principles of test reliability and validity, and be able to recognize the strengths and limitations of different types of assessment instruments (e.g. semi-structured interview, self-report, projective, task completion). They must also be familiar with a range of tests used in their area of specialization, be fully competent in standard administration and scoring procedures for tests they use routinely in their practice, and know when it is appropriate to deviate from standard practice to meet the demands of atypical testing situations or the needs of individuals with disabilities (e.g. providing written, instead of oral instructions to test takers who are hard of hearing).

Tests were historically developed, administered and interpreted without consideration of socio-cultural variables impacting test takers' performance, resulting in the systematically biased and unfair use of tests with racial, ethnic, gender, and linguistic minorities. Nowadays the field recognizes that socio-cultural variables have an inescapable influence in the testing process – from test development to decision making – and that efforts must be made to account for them. For example, testing professionals should recognize that behaviors one considers normal, typical, or functional in one socio-cultural context may be cause for concern in another, and exercise caution when interpreting test data (e.g. an inquisitive and assertive child may be perceived as emotionally healthy in one context and defiant or disrespectful in another). All testing professionals are therefore responsible for acquiring knowledge of cultural and linguistic diversity issues in testing, developing competencies for working with individuals of diverse backgrounds, and keeping aware of their cultural blind-spots. For further discussion on the impact of socio-cultural variables in assessment, see Acculturation Considerations in Personality Assessment and Culture-Free/Fair Intelligence Testing in this volume.

Lastly, it is common for testing professionals to specialize in a specific area of practice and have little or no training in other areas. They are responsible for recognizing the bounds of their training and experience, and seek consultation with other professionals if they must take on a testing assignment which they are not fully prepared to handle on their own. Additional formal training and supervised experience may be required if they want to expand the scope of their practice to a completely new area (e.g. a professional with expertise in personality assessment who wants to expand her practice to neuropsychological testing). They are also responsible for keeping up to date with developments in their areas of specialization, and obtaining continuing education for new or updated tests used in their practice.

Selection, Administration, and Interpretation of Tests

Multiple factors must be taken into account when making decisions about test selection, such as the purpose of the assessment, the specific referral question, the characteristics of the individual or group of individuals being assessed, the strengths and limitations of various types of tests, and how each contributes to the assessment process to form a comprehensive understanding of the test taker's strengths and challenges. Testing professionals should select tests that have well-established reliability and validity for assessing the constructs or domains of interest, that are relevant given the purpose of the assessment, and that are appropriate for use with the individual or group of individuals being assessed.

Test takers' knowledge about and attitudes toward testing have a significant impact on their performance and the outcome of the assessment process. Test users are responsible for developing rapport with clients, preparing them for the testing situation, and ensuring all other testing conditions are met before proceeding with test administration. For example, testing should take place in a room that is well-lit and free of distractions, and when clients are feeling well and prepared to participate in all testing activities. Test users should also provide clients with information about the purpose of testing before test administration; and discuss the nature of the tests they plan to use, what will be done with the results,

and how and when clients will receive feedback. They are also responsible for informing clients of their rights and responsibilities, discussing limits to confidentiality, and obtaining informed consent (and assent when appropriate), except when testing without consent is mandated by law.

Interpretation of testing data should proceed carefully, taking into account information obtained from multiple sources, such as clients' self-report at intake, behavioral observations, review of records, consultation with other professionals, and interviews with other informants (e.g. family members). Test users' broad knowledge, acquired over years of professional training and experience, has the greatest impact at this stage of the assessment process. They must rely not only on the test results but also on what they know about typical human development, psychopathology, multicultural psychology, and other areas of science and practice to make sense of the data. Test users must also consider their clients' current life situation, their motivations to seek services, and their attitude toward testing to determine whether the test results are valid. Test interpretation therefore requires a sophisticated skill set – the ability to review and integrate large amounts of qualitative and quantitative data from various sources, evaluate the client's performance from both nomothetic and ideographic perspectives (i.e. normative and individualized), and form a multidimensional impression of the client's current level of functioning in the domains of interest (e.g. personality, cognitive).

Handling of Testing Data

Testing data are considered sensitive client information and must be handled in a manner consistent with both legal and ethical guidelines. Testing professionals must be knowledgeable about what constitutes testing data, how such data should be stored and protected, and in which circumstances they can be released and to whom. Testing data include any information obtained during the assessment that is specific to the client, such as the client's responses, the assessor's notes, the client's raw and scaled scores, and computer generated summaries. Test materials (e.g. questionnaires, response booklets, manuals) are typically not considered testing data but they become data when containing client information.

Testing results should be described to clients in a comprehensive report, written in language free of jargon, to provide them with an integrated summary of findings, conclusions and recommendations that directly address the referral question. Testing data, without interpretation, should not be released to clients and individuals who are not trained to interpret or use them effectively. They should be kept in the client's file in a secure location, along with other confidential client information protected by law and ethical principles of professional conduct. Upon request, testing professionals may release testing data to a client, whomever the client designates, or to an entity cited in a legal document (e.g. subpoena enforced by court order); but discretion in releasing the data without interpretation must be exercised as there are circumstances when it may be appropriate to withhold testing data or components of the data. For instance, if there is evidence to suggest that releasing testing data to a client may compromise the client's safety, a compelling argument can be offered for denying the request. In situations when professionals believe that withholding data is the most appropriate course of action, they should seek consultation about the potential ethical and legal ramifications of such decisions, which may vary by state.

Conclusion

Testing can improve assessment when conducted competently and responsibly. The appropriate selection, administration, and interpretation of tests – as well as the appropriate handling of test data – is therefore the responsibility of testing professionals. Careful consideration must be given to numerous factors that can potentially impact the validity of testing protocols and their ethical use. As the field continues to evolve, testing professionals must keep well informed of current best practices in their areas of expertise, and remain aware of potential new ethical challenges (e.g. expansion of telehealth and increased demand for remote administration of tests).

Rights of Test-takers

Richard L. Miller

Texas A&M University–Kingsville

In conducting scientific research, scientists face a variety of ethical dilemmas. Because research is a complex process, well-intentioned investigators can overlook the interests of research participants, thus harming participants, and over time, causing harm to scientists, science, and society. Given the importance of ethics for the proper conduct of research, it is not surprising that many professional associations, government agencies, and universities have adopted specific rules and policies relating to research ethics. Foremost among these codes is the Declaration of Helsinki developed by the World Medical Association and later extended to cover social and behavioral science research. The declaration states that "concern for the interests of the subject must always prevail over the interests of science and society." In the United States, the National Commission for the Protection of Human Subjects of Biomedical and Behavior Research was created and is best known for the Belmont Report. This report identified three basic ethical principles and their application to research: respect for persons, beneficence, and justice.

Researchers who use tests to study human behavior have professional and legal responsibilities to those participating in their research study. As noted by the APA report on the rights and responsibilities of test-takers, these ethical and legal responsibilities must be disclosed to research participants in order to create a bond of trust between the participant and the researcher.

Five Fundamental Principles that Address the Rights of Test-takers

- Participants taking a test for research purposes must do so voluntarily and not as a result of coercion, either with the promise of inappropriate rewards or punishments.
- Test-takers need to be appropriately informed about the purpose of the test and how their personal information and test results will be used and protected.

- Test-takers should be protected from harm or any possible disadvantage as a result of taking tests for research purposes.
- Test-takers' privacy shall be protected and all personal information will remain confidential and secure.
- In order to create a climate whereby individuals are willing to participate in research, the procedures should attempt to ensure that participants are satisfied with the research experience. To do this, test-takers should be treated with courtesy, respect, and impartiality.

Five Fundamental Principles that Guide the Actions of Test Administrators

- Test administrators must be honest, transparent, and straightforward, although they are not required to divulge the hypotheses being tested in the study.
- Test administrators will subscribe to a code of conduct that requires integrity, objectivity, and quality.
- Test administrators are required to exercise judgment that is independent and professional in the design, conduct, analysis, and reporting of their research projects and activities.
- Test administrators must use tests that meet professional standards and are appropriate such as those described in the AERA, APA, and National Council on Measurement in Education's Standards for Educational and Psychological Testing, and must have appropriate training, qualifications, and experience.
- Test administrators must comply with all applicable national and international regulations governing research activities.

Testing professionals include those who develop tests, those who sell them and those who select the tests to be administered, test administrators, and those who score the tests and interpret the results. There are several sources that describe the specific responsibilities of those in the testing business who do not interact directly with test-takers, including the American Association for Counseling and Development (1989) and the Joint Committee on Testing Practices (1988).

Test-takers, along with all participants in research, are protected by additional ethical principles including those that guide the selection of participants, informed consent, confidentiality and privacy, testing vulnerable populations, and debriefing.

Recruiting Participants

One of the first ethical issues a researcher must address involves the recruitment of participants. In recruiting participants, researchers should be guided by the principles of autonomy, respect for persons, and beneficence. Specific ethical concerns with regard to recruiting participants include the use of inducements and coercion, consent and alternatives to consent, institutional approval of access to participants, and rules related to using student subject pools. It is important that researchers avoid "hyperclaiming," in which the goals the research is likely to achieve are exaggerated. It is also important that researchers do not exploit potential participants by offering inducements that are difficult to refuse.

At the same time, researchers must weigh the costs to the participant and provide adequate compensation for the time they spend in the research process.

Informed Consent

The cornerstone of ethical research is informed consent. In general, the informed consent process requires researchers to provide potential participants with information about the purpose of the research, methods to which the participant will be subjected, demands, risks, inconveniences, possible discomforts and possible outcomes of the research. Whether and how the results might be disseminated should also be described to the participant.

In all but minimal-risk research, informed consent is a formal process whereby the relevant aspects of the research are described along with the obligations and responsibilities of both the participant and the researcher. An important distinction is made between "at risk" and "minimal risk." Minimal risk refers to a level of harm or discomfort no greater than that which the participant might expect to experience in daily life. Research that poses minimal risk to the participant is allowed greater flexibility with regard to informed consent, the use of deception, and other ethically questionable procedures.

While most research with human subjects includes a documented informed consent process, it should be noted that federal guidelines permit documented informed consent to be waived if (a) the research involves no more than minimal risk to the participants; (b) the waiver will not adversely affect the rights and welfare of the participants; and (c) the research could not be feasibly conducted if informed consent were required.

Avoiding Harm: Pain and Suffering

Participants' consent is typically somewhat uninformed in order to obtain valid information untainted by knowledge of the researcher's hypothesis and expectations. Because of this lack of full disclosure, it is important that the researcher ensures that no harm will come to the participant in the research process. Types of harm that must be considered by the researcher in testing include psychological stress, feelings of having one's' dignity, self-esteem, or self-efficacy compromised, or becoming the subject of legal action. In addition to considering the potential harm that may accrue to the research participant, the possibility of harm to the participant's' family, friends, social group, and society must be considered.

While psychological research into certain processes, for example, anxiety, depends on the arousal of some discomfort in the participant, it is the responsibility of the researcher to look for ways to minimize this discomfort. Some ways that may minimize the psychological consequences of the discomfort include full and candid disclosure of the experimental procedures, providing opportunities for the participant to withdraw, and ensuring that there are no lingering ill effects of the discomfort. One particular type of lingering ill effect relates to the possibility of embarrassment that participants can experience as a result of their test performance during the research process. To protect participants from this type of harm, it is essential that researchers employ procedures to maintain confidentiality.

Maintaining Confidentiality

Confidentiality is a complex, multifaceted issue. It involves an agreement, implicit as well as explicit, between the researcher and the participant regarding disclosure of information about the participant and how the participant's data will be handled and transmitted. To avoid misunderstandings, the procedures a researcher intends to use to maintain confidentiality should be discussed with the participant prior to the beginning of data collection. The participant should be satisfied that the procedures will be sufficient to ensure his or her privacy. The participant has the right to decide what information will be disclosed, to whom it will be disclosed, under what circumstances it will be disclosed, and when it will be disclosed.

Participants must be informed about mandatory reporting requirements, for example, illegal activity, plans for sharing information about the participant with others, and the extent to which confidentiality can be legally protected. It is the responsibility of review committees to ensure that the proposed research procedures will not unintentionally compromise confidentiality, especially with participants who are vulnerable because of age, gender, status, or disability.

There are exceptions to the rule regarding confidentiality. The 1992 APA Code of Ethics allows for a breach of confidentiality to protect third parties, and several states have embraced the Supreme Court ruling in *Tarasoff v. Board of Regents of the University of California* (1976) that requires the psychologist to take reasonable steps to protect potential victims. Researchers not trained in clinical diagnosis can find themselves in a difficult position interpreting the likelihood of harm from the test results made by research participants.

Techniques to maintain confidentiality of data include data encryption and electronic security. While most quantified data are presented in aggregate form, some types of data such as video recordings and audio recordings require special care in order to protect participants' privacy. Distortion of the images and sounds can be done, but the most important safeguard is to obtain permission from the participant to use the material, including the dissemination of the findings.

Ethical Issues in Conducting Research with Vulnerable Populations

An important ethical concern considered by Institutional Review Boards is the protection of those who are not able fully to protect themselves. While determining vulnerability can be difficult, several types of people can be considered vulnerable for research purposes, including people who (a) either lack autonomy and resources or have an abundance of resources, (b) are stigmatized, (c) are institutionalized, (d) cannot speak for themselves, (e) engage in illegal activities, and (f) may be damaged by the information revealed about them as a result of the research.

One of the principal groups of research participants considered to be vulnerable is children and adolescents. In addition to legal constraints on research with minors adopted by the United States Department of Health and Human Services (DHHS), ethical practices

must address issues of risk and maturity, privacy and autonomy, parental permission and the circumstances in which permission can be waived, and the assent of the institution (school, treatment facility) where the research is to be conducted. Research with children is being conducted in what Moss and Petrie view as increasingly risky spaces. Homes, schools, and communities are popular sites of educational research, but are also the places where children are most likely to be exposed to forms of risk associated with cultural, social, political and economic forces that transform the child's understanding of the role of a particular space as a data gathering space.

Other vulnerable groups addressed in the literature include minorities, prisoners, trauma victims, the homeless, Alzheimer's patients, gays and lesbians, juvenile offenders, and the elderly, particularly those confined to nursing homes where participants are often submissive to authority.

During World War II, the United States made extensive use of prisoners. In response to a host of unethical research projects using prisoners, the Presidential Commission (n.d.) for the Study of Bioethical Issues recommended that prisoners could only be considered ethically acceptable as research subjects if the following three requirements were satisfied: (1) the reasons for involving prisoners were compelling, (2) conditions of equity in selection were observed, and (3) the prison lived in could be characterized by a great deal of openness in which a prisoner could exercise a high degree of voluntariness.

Alcohol and substance abusers and forensic patients present particular problems for obtaining adequate informed consent. The researcher must take into account the participant's vulnerability to coercion and competence to give consent. The experience of the investigator in dealing with alcoholics and drug abusers can be an important element in maintaining ethical standards related to coercion and competence to give consent.

One final vulnerable population addressed in the literature is the cognitively impaired. Research with these individuals raises issues involving adult guardianship laws and the rules governing proxy decisions. The question is: who speaks for the participant? Research with vulnerable participants requires the researcher to take particular care to avoid several ethical dilemmas including coercive recruiting practices, the lack of confidentiality often experienced by vulnerable participants, and the possibility of a conflict of interest between research ethics and personal ethics.

Debriefing

Debriefing provides the participant an opportunity to discuss the findings of the study. The need to adequately debrief participants in a research study is a clear ethical responsibility of the investigator although it is still the exception rather than the rule. Debriefing can serve four purposes. It can (a) remove fraudulent information about the participant given during the research process, (b) desensitize subjects who have been given potentially disturbing information about themselves, (c) remove the participants' negative arousal resulting from the research procedure, and (d) provide therapeutic or educational value to the participant. Even participants who are screened out of a study or voluntarily withdraw from a study should be debriefed and told why they might have been eliminated from the

study. It has also been suggested that a description of the debriefing procedure be included in any scientific publication of the research.

While the rights and responsibilities described in this entry are not legally based, they have been endorsed by the professional societies involved in psychological testing and by the institutions that employ those involved in the administration of tests. Those institutions include colleges and universities, schools, human service agencies, etc. The goal of the entry was to inform and to help educate both test-takers and test administrators about the ethical expectations involved in testing, especially testing for research purposes.

Validity, Issues of

Karlye A. Phillips[1], April L. Brown,[2] and A. Nayena Blankson[1]

[1] *Spelman College*
[2] *Emory University*

Validity Defined

Imagine having a conversation with a friend. This friend tells you that she was cast as the lead actress in a new action packed thriller. You believe that the information given is accurate because your friend is trustworthy. In a similar vein, we can believe that results of psychological tests are accurate if those measures are trustworthy. This is the essence of test validity.

Whereas reliability is a measure of the consistency of a test, validity refers to the accuracy of measurement. A test's validity answers the question "Does the test measure what it is intended to measure?". Referring to the example above, validity coefficients provide a numerical value regarding the extent to which we can trust the results of a measure. At the most basic level, tests are validated by demonstrating that scores are true indicators of the presence of the trait or construct of interest.

There are several approaches to establishing test validity, but most methods involve obtaining a validity coefficient through performing correlational analyses. Though validity is usually obtained empirically, there is a special case of validity called face validity, which evaluates whether the test can be trusted at "face value." That is, does the test look like it is measuring what it is intended to measure? If so, then the test is said to possess face validity. For example, if the first question on a math achievement test is "5 + 4 = ____," one can conclude that the item looks like it measures math achievement. This seemingly superficial indicator of validity can affect the attitude of test takers toward a test. For example, if the first item on the math test instead stated, "Do you enjoy ham sandwiches?" the face validity of the test would be lower because the item does not appear to measure what it is intended to measure. Moreover, the test taker might not approach the test with the same level of seriousness, and ultimately, the results of the test may not be trustworthy. Thus, although, face validity is not quantifiable and is often not considered a real type of validity, it has important implications for other aspects of the test's validity.

One method of establishing whether a test is valid is content validity. Content validity provides information regarding the linkage between the content of the test and the definition of the construct that is being measured by the test. Content validity is especially important for achievement tests, which are intended to measure an individual's level of knowledge in some area. A two-way table of specifications that has two dimensions covering content topics and mental processes is typically used to represent a content area. In fact, Bloom's cognitive classification scheme is widely used, as it conveniently allows validity to be established by matching a test with the specifications of the table (Hogan, 2015). Content validity is also more easily applied to employment tests, where the content area is composed of information regarding the necessary skill set and knowledge required by a job. Although it is quite difficult to truly define the content area for most constructs, content validity is nevertheless an appropriate technique for assessing the validity of most tests. Content validity is not usually empirically determined; it is instead often determined by judgment of a panel of experts. Other methods for establishing validity are more readily empirically determined.

One such method is criterion-related validity, which involves comparing the examinees' test performance with other measures or procedures that have already been deemed valid (i.e., the "criterion"). There are two approaches to criterion-related validity, namely predictive validity and concurrent validity. Predictive validity is the extent to which a test score can predict status on some other criterion that will be achieved in the future, whereas for concurrent validity, test performance is correlated with current status on a criterion. In either case, a correlation coefficient is often computed.

Essentially, all validity evidence can be discussed in terms of construct validity. The goal of establishing construct validity is to determine the extent to which a test measures the intended construct, which sounds very much like the basic definition of validity. Evidence of content and criterion-related validity provide some evidence of construct validity, but there are several additional ways to establish construct validity.

For example, construct validity can be established using another test. In this manner, test scores from another test that has already been deemed valid are correlated with scores of the focal test. If scores from the focal test correlate well with scores from an already established test measuring the same construct, then the new test is said to have convergent validity. In addition to demonstrating that a test is measuring what it purports to measure, it is also useful to demonstrate that a test is *not* measuring another construct. Discriminant validity refers to the lower correlation between the focal test and a criterion test that *does not* measure the same construct of interest. For example, one may want to demonstrate that a test designed to measure personality is *not* measuring depression. Scores from the personality test should correlate more strongly with another personality test (convergent validity) than with a test measuring depression (discriminant validity). Discriminant validity provides researchers with information regarding how much the test differs from a test measuring a different construct. A multi-trait multi-method approach can be used to simultaneously confirm the convergent and discriminant validity of a test (Campbell & Fiske, 1959).

Construct validity can also be assessed by examining the internal structure of the test; intervention or experimental changes; developmental changes; or group differences (Hogan, 2015). More specifically, factor analyses can be conducted to determine the underlying dimensions of a test. Construct validity can also be investigated with experiments or interventions. If the construct that the test is intended to measure is subject to

changes due to interventions or experimental manipulation, then an experiment or intervention can be conducted to see if after the intervention individuals in the experimental group score differently compared to those in the control group. If the construct is subject to developmental or age changes, then a study examining age differences in scores or age changes over time can be conducted to establish construct validity. Lastly, if certain groups are expected to differ on the construct, then a study can be conducted to examine group differences on the test. To the extent that expected group differences are observed on test scores, then there would be some evidence of construct validity.

In sum, validity is perhaps the most important aspect of tests. Validation is an on-going process, and a test can be valid for some purposes (e.g. for use with children), but not for other purposes (e.g. for use with adults). Content validity, criterion-related validity, and construct validity are all classic methods of providing evidence that a test is valid.

[3]*Clarkson University*

Within the literature, aggression is defined as behavior intended to cause harm, injury, or pain to others through physical, verbal, or indirect means. Although often assessed simultaneously, aggression differs from constructs such as anger or hostility which are typically antecedents of aggression. Violence also differs from aggression as it is characterized as (1) a behavioral response in reaction to an emotional response to anger and (2) a cognitive reaction hostility in situations usually characterized by annoyance, frustration, or perceived wrongdoing. Additionally, violence is often classified as a more extreme aggressive act that is physical in nature resulting in substantial harm or injury to oneself or another person. Despite the varying conceptual distinctions between these constructs, the overlap and colloquially understood uses for them influence common assessments of aggression to co-assess and/or include the constructs of anger, hostility, or violence.

Aggression can be assessed through a variety of research tools including self- or other-report questionnaires and/or interviews, projective tests, and behavioral measures. In addition, aggression can be assessed through observational studies in which trained observers determine an operational definition of aggression (e.g. number of times hit or kicked, number of times rumors are spread) and then observe and record the target person's behavior. In this entry, we define aggression and seek to provide examples of commonly used self- and other-reports and behavioral assessments; we omit projective tests from this entry due to the infrequency of their use. The highlighted entries are not an exhaustive collection of aggression assessment tools but rather are meant to provide a brief introduction to frequent assessments used.

Forms of Aggression

Given the numerous scenarios from which aggression can arise, the literature suggests various ways to conceptualize aggression. First, aggression can be defined based on the time frame during which aggressive behaviors occur. That is, those aggressive behaviors that are acute or isolated are known as *state* aggressive behaviors. Behaviors such as these are usually attributed to situational circumstances. In contrast, aggressive behaviors that persist over longer durations of time are known as *trait* aggressive behaviors and are often attributed to an individual's personality.

Second, aggression can be defined based on whether the target is physically present (i.e. whether the target is present and is intending to harm the individual). Such cases are known as *direct or overt acts of aggression* (e.g. hitting someone, verbal insults). In contrast, aggressive behaviors that occur when the target is not physically present are known as *indirect or covert aggression* (e.g. spreading rumors). This form of aggression is intended to harm the target by damaging the target's social standing or reputation. *Displaced aggression* occurs when aggressive behaviors are directed at a third, uninvolved party.

Finally, aggression can be defined based on the primary motivation. Aggressive behaviors that are premeditated and planned are referred to as *instrumental or proactive aggression*; this form of aggression is typically motivated by a desire to obtain a particular outcome (e.g. increase perpetrators' status or power or to gain money or recognition). Although targets are harmed by this type of aggressive behavior, the primary motivation of the aggressor is to reach a particular outcome rather than inflict harm or cause the target pain. Aggressive behaviors that are impulsive and unplanned are referred to as *reactive or hostile aggression*; this form of aggression is motivated by emotions such as anger or hostility and is primarily intended to inflict harm on the target.

Self-reports of Aggression

It is worth noting that although aggression is often conceptualized in the above ways, there is substantial overlap in the forms of aggression. For example, overt aggression can be reactive or instrumental in nature. Assessments of aggression often measure multiple dimensions of aggressive behaviors. In this section, we highlight examples of common self- and other-reported assessments of aggression.

The Aggression Questionnaire (Buss & Perry, 1992) is a 29-item scale used to assess trait levels of physical aggression, verbal aggression, anger, and hostility. The Life History of Aggression interview is used to assess the frequency of aggression (i.e. verbal aggression, aggression directly at objects, non-specific fighting, and physical aggression) across a person's life.

The Positive and Negative Interpersonal Behaviors Inventory is a 40-item scale designed to assess the frequency of direct and indirect aggression and victimization as well as prosocial/non-aggressive behaviors.

The Adult Scale of Hostility and Aggression: Reactive/Proactive is a 58-item scale used to assess a caregiver's reports of verbal aggression, physical aggression, hostile affect, covert aggression, and bullying in adults with developmental disabilities.

The Impulsive/Premeditated Aggression Scale is a 30-item questionnaire used to assess aggression, specifically premeditated aggression (i.e. instrumental aggression) and impulsive aggression (i.e. reactive aggression), that occurred within the past six months.

The Staff Observation Aggression Scale (SOAS) is used to assess aggressive behavior in patients (particularly involuntarily admitted patients) in inpatient mental illness programs. The SOAS is used to assess (1) factors that provoked aggressive behavior, (2) specific aggressive behavior, (3) the target of the aggression, (4) consequences for the target of the aggression, and (5) measures taken to stop the aggressive behavior. Although meant to capture a range of aggressive behavior, the SOAS tends to be used for reporting moderate to severe aggressive behaviors.

The Reactive-Proactive Questionnaire (Raine et al., 2006) is a 23-item survey used to assess proactive and reactive aggression. This scale can be used with children with a reading age of 8 years.

The Achenbach also contains a subscale to assess self-reported aggressive behavior in children (Child Behavior Checklist) and youth (Youth Self-Report) as well as teacher-reported aggression in children (Teacher's Report Form).

Denson, Pedersen, and Miller (2006) examined trait differences in displaced aggression through the 31-item Displaced Aggression Questionnaire. This questionnaire measures affect, behavioral, and cognitive dimensions of displaced aggression, namely angry rumination, behavioral displaced aggression, and revenge planning (respectively).

Behavioral Assessments of State Aggression

There are several behavioral paradigms used to assess indirect aggression. For example, in the jelly bean task (e.g. Lee et al., 2012), participants are presented with a variety of good-tasting jelly beans (e.g. cherry, chocolate, pie) and bad-tasting jelly beans (e.g. vomit, earwax, dirt) in a clearly labeled container. Participants are told they are working with another participant and that their task is to select jelly beans for another participant to taste test. Indirect aggression is assessed by the number of total good-tasting (i.e. no aggression) and bad-tasting (i.e. aggression) jelly beans selected (including the ratio of good-tasting to bad-tasting jelly beans).

Similarly, in the drink task, participants select one of six substances (i.e. sugar, apple juice, lemon juice, salt, vinegar, and hot sauce) for a supposed other participant to taste test; they are told that the supposed participant rank-ordered the substances from most preferred (sugar) to least preferred (hot sauce). Indirect aggression is assessed by which substance is selected (hot sauce is most indirectly aggressive; sugar is not aggressive) and amount of substance given. In another variation of this task, commonly referred to as the hot sauce task, participants learn that the supposed other participant dislikes hot sauce; aggression is assessed by the amount of hot sauce participants decide to administer.

Overt aggression can also be assessed through behavioral paradigms. In a classic paradigm (Bushman & Baumeister, 1998), participants are asked to write an essay and are told their essay will be exchanged with another participant's essay for feedback. In actuality, participants are randomly assigned to receive positive feedback (e.g. no suggestions; great essay!) or negative feedback (e.g. one of the worst essays I've ever read). After receiving this

feedback, participants engage in another competition task with the confederate and have the opportunity to deliver various degrees of white noise. Aggression is assessed by the degree of severity/aversiveness of the white noise. This paradigm can also be adjusted to assess indirect aggression by having the participant work with a third participant or confederate after receiving negative feedback from the initial confederate. Similarly, displaced aggression can be assessed by providing participants opportunities to aggress against a third, uninvolved person by thwarting their ability to earn money (e.g. Leander & Chartrand, 2017) or providing more challenging problems for the third person (e.g. Saleem, Anderson, & Bartlett, 2015).

The Point Subtraction Aggression Paradigm (PSAP) is also used to measure aggressive behaviors. Participants are paired with a supposed other participant and are given several behavioral response options (respond to earn money, protect money, or deduct money from the supposed other participant). Deducting money from the supposed other participant is considered an aggressive act. To provoke participants, the computer (i.e. the supposed other participant) simultaneously deducts the participant's money regardless of participants' choices. Slightly different versions of the PSAP can be administered in order to examine instrumental and reactive aggression.

Conclusions

Although aggression is defined in terms of behavioral acts designed to harm, injure, or inflict pain on an individual, some assessments also include several related features including measures of affect (primarily anger or frustration) and cognition (particularly hostility). In addition to observing and recording aggressive behaviors, self- and other-reports and behavioral assessments are commonly used to measure aggression. Even with these tools, it is important to note that aggression is a multifaceted construct that may be difficult to assess using only one measure. Additionally, the highlighted assessments, although useful to quantify how aggressive an individual is, do not directly capture *why* the aggressive behavior occurred. Regardless of these shortcomings, the number of assessments created to conceptualize aggression suggests the broad impact this topic has had on the research literature. The current entry, in addition to providing frequently used assessments of aggression, also highlights the essentiality of assessing both the way aggression is evidenced as well as the context in which it occurs.

Anger and Hostility, Assessment of

Kyle Z. Pasquariello[1], Alanna Wormwood[2], and Jennifer M. Knack[2]

[1]*SUNY University at Buffalo*
[2]*Clarkson University*

Anger and hostility are multifaceted constructs composed of affective and cognitive components. Despite periodically being used interchangeably due to the overlap in affective and cognitive components, anger and hostility differ in the emphasis given to each component. Anger is typically conceptualized as an emotion (i.e. affect) whereas hostility is generally considered as an attitude (i.e. cognition) often resulting from anger. In this entry we define anger and hostility and present tools used to assess these constructs.

Defining Anger and Hostility

Anger, one of the basic human emotions, is typically defined as a subjective negative affective reaction experienced when a person perceives a malevolent situation or interaction. The intensity of the subjective emotional response varies from mild (e.g. annoyance) to intense (e.g. rage) affect. Anger is also characterized by physiological responses such as changes in sympathetic arousal (e.g. increased heart rate, tensed muscles), hormone levels (e.g. increased testosterone), behavioral responses (e.g. facial expressions), and cognitive factors (e.g. irrational beliefs).

Anger is classified as an approach emotion that propels people to engage with or move toward a situation (Harmon-Jones, 2003). Anger can be a beneficial emotion that enables people to establish boundaries or escape a dangerous situation (Videbeck, 2006). Despite being classified as an approach emotion, expressions of anger can be inhibition oriented or approach oriented. Individuals with an inhibition orientation withdraw and seclude themselves whereas people with an approach orientation engage further to express anger outwardly (Bridewell & Chang, 1997). Although behavioral responses are widely considered an indication of anger, such responses are typically labeled as aggression rather than anger.

Hostility is conceptualized as a trait with emphasis placed on cognitive components. Hostility is regarded as an attitude marked by a strong negative evaluation of the target (e.g. being dishonest, mean). Hostility is marked by cynicism and mistrust of people and strong negative affect for the target. Hostile people often perceive others as sources of transgressions and devalue people's motives for their actions. People who are high on hostility attempt to force the world and people to conform to their perceptions of "'what ought to be." Hostility is often marked by physical (e.g. hitting, harming oneself or others) and non-physical (e.g. verbal comments, blackmail) behavioral responses. Hostility is a robustly accepted antecedent of aggressive and vindictive behavior (as opposed to being defined by aggressive behavior).

Although often correlated, anger and hostility are conceptually different. Anger is an emotional reaction to a negative, provocative situation whereas hostility is a cognitive trait characterized by negative evaluations and affect toward others. Despite the emphasis of anger being affective and hostility being cognitive, both anger and hostility are multidimensional and include internal (e.g. affective, cognitive, physiological) and external (behavioral) components. Anger, like other emotional responses, tends to be short in duration whereas hostility tends to be longer in duration. Both anger and hostility can range in intensity from mild to extreme. Given the multidimensional nature of anger and hostility, there are a variety of assessments designed to measure self-reports of affect and cognition, physiological changes, and behavioral responses. Below we provide examples of commonly used assessments; our examples are not an exhaustive collection of the numerous ways of assessing anger and hostility.

Assessment of Anger

Although we present anger assessments individually, multiple modalities of anger measurement are often used concurrently. In particular, due to the subjective affective nature of anger self-report, assessments are typically collected in conjunction with behavioral and physiological assessments in order to be able to interpret the latter.

Self-Reports

The Behavioral Inhibition System (BIS)/Behavioral Activation System (BAS) Scales were derived from theories postulating the respective two motivational systems underlying human behaviors. The scales contain 24 items rated on a 4-point Likert scale and are used to understand the motivational systems of emotions such as anger. Since anger is typically considered an approach emotion, the three BAS subscales (i.e. Drive, Fun Seeking, and Reward Responsiveness) are typically examined. The BIS/BAS scale is commonly used during experimental manipulations of anger in an attempt to interpret physiological and behavioral responses to anger.

The 60-item Novaco Anger Scale (NAS) is used to assess people's experience of anger by measuring (1) cognitive components (e.g. anger justification, rumination, hostile attitude, suspicion), (2) arousal (e.g. anger intensity, duration, somatic tension, irritability),

(3) behavior (e.g. impulsive reaction, verbal aggression, indirect expression), and (4) anger regulation (e.g. ability to regulate thoughts, self-calm, and engage in constructive behavior). The 25-item NPI is used to determine the type of situations that elicit anger including situations in which there is disrespectful treatment, unfairness, frustration, annoying traits of others, and irritations.

The Multidimensional Anger Inventory (MAI) is used to assess anger arousal (e.g. frequency, duration, magnitude), anger eliciting situations, hostile outlook, and anger expression (i.e. anger-in and anger-out). Despite the focus on anger, this assessment uses anger and hostility interchangeably. Similarly, the State-Trait Anger Expression Inventory (STAXI) is a 44-item measure of experience and expression of anger that is a compilation of the State-Trait Anger Scale (STAS) and the Anger Expression Scales (AX). The STAXI is used to assess intensity of state anger, frequency of trait anger, expression of anger, anger suppression, and anger regulation.

Behavioral Assessments

A number of paradigms are used to induce anger in participants (i.e. experimental manipulations) in order to assess behavioral responses. One paradigm used to induce anger involves participants playing a rigged board game with a confederate who always cheats to win. One behavioral response commonly examined is facial expressions. Using the facial action coding system (FACS), anger typically manifests as lowered eyebrows, wide open eyes, parted lips that expose teeth, and stretched lip corners; more recent assessments have examined micro-expressions of anger. Other non-verbal responses commonly examined include aggressive behaviors such as slamming objects (Capaldi & Clark, 1998). In addition, behavioral assessments of anger can include common verbal behaviors (e.g. louder voice, change in tone). Researchers also measure antecedent behavioral cues of anger such as social withdrawal behaviors or displays of frustration (e.g. crying, teeth grinding, fist clenching).

Physiological Assessments

Although it is widely accepted that physiological changes are not unique to anger, it is still common to assess physiological responses. Cardiovascular responses (i.e. cardiac output, ventricular contractility, total peripheral resistance) are typically assessed through EKG screening or blood pressure. In addition, galvanic skin response (i.e. skin conductance) is also commonly assessed. Although physiological measurements such as blood pressure and heart contractility are commonly used, there is debate about the reliability of these measures because many variables affect these measures (e.g. Type A personality, amount of exercise, stress). Researchers have also examined hormone levels (e.g. testosterone), neurotransmitters, and serum lipids (e.g. serum cholesterol, low-density lipoproteins). Associations between brain activation and anger have been widely studied through EEG, fMRI, and PET (Phan et al., 2002). In line with BIS/BAS motivational systems, participants who are angry exhibit higher left relative to right frontal cortical activity when angry.

Assessment of Hostility

Similar to anger, the nature of hostility requires researchers and clinicians to measure multiple dimensions. Most common are behavioral assessments, physiological assessments, and self-report hostility surveys.

Self-Reports

The Buss-Durkee Hostility Inventory (BDHI) is a 66-item true-false scale composed of seven subscales: assault, indirect hostility, verbal hostility, irritability, negativism, resentment, and suspicion. However, subsequent research has indicated that these subscales could be reduced to aggression (assault, indirect aggression, irritability, verbal aggression) and hostility (resentment, suspicion) or to overt hostility (assault, verbal aggression) and covert hostility (resentment, suspicion). The 29-item Buss-Perry Aggression Questionnaire (BPAQ) was developed to address the psychometric and theoretical shortcomings of the BDHI and consists of four subscales including hostility, anger, verbal aggression, and physical aggression.

The Cook-Medley Hostility Inventory is a 50-item self-report scale used to assess hostility and character traits among teachers who did not get along with their students; it is now commonly used when assessing associations between hostility and cardiovascular health. Some researchers have identified six subscales including hostile attractions, cynicism, hostile affect, aggressive responding, social avoidance, and others; other researchers have identified two factors (cynicism, paranoid alienation) or four factors (cynicism, hypersensitivity, aggressive responding, social avoidance) (Smith, Sanders, & Alexander, 1990). Despite the inconsistency in number of factors, this scale continues to be widely used.

Behavioral Assessments

Because hostility is often characterized by an externalized reaction to internal stimuli or emotion, behavioral assessments are often used to measure several subclasses of hostility such as assault (i.e. physical violence against others), indirect hostility (i.e. gossiping, temper tantrums), irritability (i.e. quick temper, grouchiness, rudeness), resentment (i.e. jealousy, hatred), suspicion (i.e. distrust, planning harm), and verbal hostility (i.e. threatening, cursing). Paradigms can be used to provoke hostile reactions that are classified as one or more of these subclasses of hostility; the magnitude and duration of the particular reaction are used to determine the participant's hostility level. Another popular way to measure hostility is through interview based assessments popularized by the Western Collaborative Group Study (WCGS); trained interviewers make judgments of hostility based on participants' responses during a standard interview.

Physiological Assessments

Although it is difficult to distinguish physiological changes due to hostility from similar affective states such as anxiety or anger, researchers have attempted to elicit a hostile

reaction via provoking situations and then measuring the physiological changes that occur. Among the most common physiological changes examined are heart rate and blood pressure. Many researchers argue that hostility predicts a higher magnitude and longer duration of elevated blood pressure and heart rate (Frederickson et al., 2000). However, as mentioned above, it is difficult to determine whether these physiological changes are due to changes of hostile ideations or other factors known to impact these measures (e.g. stress, exercise).

Conclusions

Although related constructs, anger and hostility are conceptually distinct. Anger is an emotional reaction to situational stimuli that is generally short in duration whereas hostility is a trait characterized by a strong negative evaluation of target. Both anger and hostility are antecedents for aggressive and violence behavior. Although assessments of anger and hostility that measure each of the multiple dimensions (e.g. affective, cognitions, behavioral responses, physiological responses) of these constructs exist, subjective self-reports are vital given the subjective nature of anger and hostility. Thus, even when using physiological or behavioral assessments of anger and hostility, it is important to include self-reports in order to capture the subjective nature of the constructs.

Anxiety, Assessment of

Kimberly B. Dasch-Yee

Holy Family University

Anxiety is conceptualized as including both physiological arousal and psychological worry (see Anxiety for a more thorough discussion on conceptualizations of anxiety). Reliable and valid assessment of anxiety is essential in both clinical and research settings. Numerous measures have therefore been created to assess anxiety. As anxiety can be conceptualized in a number of ways, and is measured in a number of different populations, a variety of measures are needed in order to assess anxiety in these diverse settings. Some measures of anxiety are designed to be used in clinical (psychology or psychiatric) populations, whereas others are designed more for hospital (medical) populations, or general (including student) populations. In addition, measures differ on whether they measure anxiety as a state (temporary) or a trait (long lasting). Measures also differ on how they operationally define anxiety, that is, what specific symptoms or characteristics of anxiety they measure. For example, some focus on more physiological components of anxiety, whereas other measures avoid physiological components. In addition, some measures focus exclusively on anxiety, while others measure anxiety and depression, or anxiety, depression (see Depression for more on assessment of depression), and stress (see Individual Differences in Coping with Stress for more on individual differences in coping with stress). Several commonly used anxiety measures are described below. Included with the description of each measure are a discussion of the population(s) for which the measure may be most appropriate and a discussion of some of the strengths and weaknesses of each.

Beck Anxiety Inventory

The Beck Anxiety Inventory (BAI; Beck, Epstein, Brown, & Steer, 1988) is a self-report measure designed to measure anxiety in clinical populations. The BAI has 21 items. Respondents rate how much they are affected by each symptom of anxiety on a 4-point Likert-type scale from 0 (*Not at all*) to 3 (*Severely – I could barely stand it*). The resulting total score can range from 0 to 63. Examples of items on the BAI include: "Numbness or

tingling," "Feeling hot," "Wobbliness in legs," "Unable to relax," and "Fear of the worst happening." The BAI has strong internal consistency and test-retest reliability. A particular strength of the measure is that it was developed to reliably discriminate and avoid overlap between anxiety and depression. Indeed, it has been found to reliably discriminate between those diagnosed with anxiety disorders (such as panic disorder and generalized anxiety disorder) and those diagnosed with depressive disorders (such as major depressive disorder and dysthymic disorder). In addition, it was designed for use with psychological or psychiatric populations, unlike other measures that were developed with student samples. However, a limitation is that most of the anxiety symptoms measured by the BAI are consistent with panic attack symptoms, but other symptoms of anxiety, such as worry or muscle tension are not measured.

Hamilton Anxiety Scale

The Hamilton Anxiety Scale (HAM-A; Hamilton, 1959) is a clinician-report measure of anxiety designed to measure the level of anxiety in individuals diagnosed with an anxiety disorder. The clinician rates the individual on 14 subscales: Anxious Mood (worries, fearful anticipation), Tension (fatigability, inability to relax), Fears (of specific situations), Insomnia (difficulty falling asleep, unsatisfying sleep), Intellectual (difficulty with concentration and memory), Depressed Mood (loss of interest, lack of pleasure), General Somatic Muscular Symptoms (pains and aches, stiffness), General Somatic Sensory Symptoms (tinnitus, blurring of vision), Cardiovascular Symptoms (tachycardia, palpitations), Respiratory Symptoms (pressure or constriction in chest, choking feelings), Gastrointestinal Symptoms (difficult in swallowing, vomiting, looseness of bowels), Genitourinary Symptoms (frequency or urgency of urination or sexual symptoms), Autonomic Symptoms (dry mouth, flushing, tendency to sweat), and Behavior at Interview (fidgeting, restlessness or packing, tremor of hands). Each scale is rated on a 5-point Likert-type scale from 0 (*None*) to 4 (*Severe*). The symptoms can be grouped into two subscales: psychic anxiety (tension, fears, insomnia, anxiety, intellectual, depression, and behavior at interview) and somatic anxiety (gastrointestinal, genitourinary, respiratory, cardiovascular, general somatic muscular and sensory symptoms, and autonomic symptoms). Interrater reliability has been found to be adequate. A strength of the HAM-A is that it is a clinician rating scale, meaning that the clinician completes the measure after interviewing the patient, whereas most measures of anxiety are self-report. However, the measure overlaps with features of depression, making the HAM-A a less specific measure of anxiety.

Depression Anxiety Stress Scales

The Depression Anxiety Stress Scales (DASS; Lovibond & Lovibond, 1995) are self-report measures of symptoms of depression, anxiety, and stress appropriate for use in clinical and non-clinical populations. The full DASS consists of 42 items, with 14 items on each subscale. There is also a 21-item version with seven items on each subscale. Respondents rate the degree to which each item applies to them on a 4-point Likert-type scale ranging from 0 (*Did not apply to me at all*) to 3 (*Applied to me very much, or most of the time*). While the Anxiety subscale measures autonomic arousal, skeletal musculature effects, situational

anxiety, and subjective experience of anxious affect, the Stress scale measures chronic non-specific tension and arousal. The anxiety subscale measures symptoms more unique to anxiety, such as physiological hyperarousal, while the stress subscale measures symptoms common to both anxiety and depression, such as tension and irritability. Items on the Anxiety subscale include "I was aware of the action of my heart in the absence of physical exertion (e.g. sense of heart rate increase, heart missing a beat)," "I experienced trembling (e.g. in the hands)," "I was worried about situations in which I might panic and make a fool of myself," "I felt I was close to panic," and "I was scared without any good reason." Items on the Stress subscale include "I found it hard to wind down," "I felt that I was using a lot of nervous energy," "I found myself getting agitated," "I tended to over-react to situations," and "I was intolerant of anything that kept me from getting on with what I was doing." Internal consistency has been found to be strong. A strength of the DASS is that it was developed in particular to discriminate between the constructs. As a result, there is less overlap between the subscales than there is in other measures.

Hospital Anxiety and Depression Scale

The Hospital Anxiety and Depression Scale (HADS; Zigmond & Snaith, 1983) measures anxiety and depression in non-psychiatric medical populations. The 14-item HADS has seven items that assess anxiety and seven items that assess depression. The measure was normed using medical patients and is particularly well-suited for use with such a population. The measure was designed to be brief, so it could be completed quickly in a medical setting. A common concern with measuring psychological symptoms in medical patients is that the scores on the psychological measures are often affected by physical illness symptoms. The HADS was therefore developed without items that would be related to both psychological disorders and physical illness, like dizziness and headaches. As a result, the HADS measures the psychic symptoms of anxiety and depression rather than the somatic symptoms. Respondents rate each item on a 4-point Likert-type scale ranging from 0 to 3, with a higher score indicating more of the symptom described. A score higher than 10 on either scale indicates a definite case, a score between 8 and 10 indicates a doubtful case, and scores below 8 on either scale are considered to be non-cases. Items on the Anxiety subscale include "I feel tense or wound up," "I get a sort of frightened feeling as if something awful is about to happen," "Worrying thoughts go through my mind," "I get sudden feelings of panic," and "I can sit at ease and feel relaxed" with the last item being reverse coded. Internal consistency was found to be strong. A strength of this measure is that it does not include somatic symptoms which prevents an overlap between medical and psychological symptoms. Further, the anxiety and depression subscales were developed to maximize their distinction, so there would be less overlap between the subscales than there may be in other measures.

State-Trait Anxiety Inventory

The State-Trait Anxiety Inventory (STAI; Spielberger, Gorsuch, Lushene, Vagg, & Jacobs, 1983) measures anxiety as both a temporary state and a longer term trait. Trait anxiety is conceptualized as a relatively stable individual difference in susceptibility to anxiety.

A person high in trait anxiety would be more likely to perceive a situation as dangerous or threatening, and would respond to such situations with greater evaluation and intensity in their more temporary state anxiety. Therefore, a person with high trait anxiety would have more frequent elevations in state anxiety. However, whether someone with high trait anxiety experiences high state anxiety at any given time will depend on how dangerous or threatening they perceive the specific situation, which will be affected by the person's past experiences. The STAI has 40 items, 20 each on the Trait and State scales. Respondents rate their anxiety on a 4-point Likert-type scale. On the Trait Anxiety Scale, 1 = *Almost Never* and 4 = *Almost Always*. On the State Anxiety Scale, 1 = *Not at All* and 4 = *Very Much So*. Some items on both scales are reverse coded. The Trait Anxiety Scale asks respondents to indicate how they "*generally* feel," and includes items such as "I feel nervous and restless," "I feel like a failure," "I feel that difficulties are piling up so that I cannot overcome them," "I feel satisfied with myself," and "I feel pleasant," with the last two items being reverse coded. The State Anxiety Scale asks respondents to indicate how they "feel *right* now, that is, *at this moment,*" and includes such items as "I am tense," "I am presently worrying over possible misfortunes," "I feel frightened," "I feel relaxed," and "I feel calm," with the last two items being reverse coded. Test-retest reliability was found to be strong for the Trait Anxiety Scale. Test-retest reliability was found to be lower for the State Anxiety Scale, but that is consistent with the conceptualization of state anxiety being a temporary state. Internal consistency was found to be strong from both scales. The STAI is appropriate for use in both clinical and non-clinical populations. The STAI is unique in that it measures both trait anxiety consistent with personality and individual differences as well as state anxiety consistent with temporary responses to current events.

Jealousy, Assessment of

Reneé R. Boburka

East Stroudsburg University

Jealousy has been defined as a response – cognitive, emotional, or behavioral in nature – to a threat to one's relationship or self-esteem by a potential rival, which motivates behavior aimed at countering the threat (White, 1981). Specifically, people should be most jealous of those rivals who are a significant threat to their self-esteem, as well as a threat to the loss of their relationships. The outcomes of jealousy can be quite varied, ranging from potentially negative (e.g. conflict, dating violence, relational dissatisfaction) to positive (e.g. increased relational satisfaction and commitment). Additionally, jealousy has been shown to be related to various personality traits, such as neuroticism, extraversion, anxiety, rigidity, and hostility.

Theories of Jealousy

Evolutionary theorists hypothesize that men and women differ in what triggers their jealousy. Buss, Larsen, Westen, and Semmelroth (1992) suggest that jealousy exists mainly due to its relational and mating benefits. Further, they propose that when forced to choose between whether a partner's sexual versus emotional infidelity would be more distressing, men are more likely to be jealous of sexual infidelities, due to the potential for paternity uncertainty. Women, on the other hand, are more likely to be jealous of emotional infidelities, given that a woman should be more concerned with a partner's commitment and investment to support her children and emotional infidelity may signify a man's lack of relational commitment and the possible diverting of his investments to the children of a rival. Empirical tests of sex differences found by the evolutionary theory have typically used a forced-choice response format in which participants had to identify which of two types of infidelity scenarios would cause them the most distress (emotional versus sexual). Buss et al. (1992) also found similar results using physiological distress measures (e.g. electrodermal response, heart rates). However, critics for this type of measure argue that psychophysiological measures do not convincingly measure jealousy.

Additional research that potentially supports evolutionary sex differences in jealousy was conducted by Sagarin, Becker, Guadagno, Wilkinson, and Nicastle (2012) when they demonstrated that sex differences in jealousy for heterosexual women and men tended to disappear among lesbians and gay men, as well as among heterosexual women and men when they considered same-sex infidelities. Also, lesbians and gay men showed no sex differences, regardless of whether the infidelity was opposite-sex or same-sex. Sagarin et al. (2012) argue that this pattern of findings supports an evolutionary reproductive threat-based model of jealousy in that the sexes only differ when reproductive outcomes are at risk.

Many researchers have challenged Buss et al.'s theory. For instance, DeSteno and Salovey (1996) found no sex difference when participants were asked to rate their jealousy on a Likert-type scale in response to sexual and emotional infidelities. Sagarin, Becker, Guadagno, Nicastle, and Millevoi (2003) presented similar emotional and sexual infidelity scenarios and, using continuous 10-point scales, asked participants to indicate their feelings of jealousy. They found that women reported more intense jealousy for both types of infidelity compared to men, with a bigger difference for emotional infidelity. DeSteno, Bartlett, Braverman, and Salovey (2002) argued that using a forced-choice format to measure jealousy is problematic in that participants have to make a distinct choice between the different hypothetical infidelity scenarios, which often results in misleading differences between the sexes. When jealousy is assessed using non-forced choice, continuous scales, sex differences typically do not emerge, and when these same individuals then complete a forced-choice scale, the sex difference appears again (DeSteno et al., 2002). Further evidence contrary to evolutionary sex differences was also discussed by Harris (2003) who, after a review of the research, contends that her meta-analytic findings do not support a significant sex difference in response to emotional versus sexual infidelity. To further complicate matters, a meta-analysis by Sagarin, Martin, Coutinho, Edlund, Patel, Skowronski, and Zengel (2012) examining numerous independent samples using continuous measures revealed that significant sex differences in jealousy may not be an artifact of the forced-choice format.

Other researchers have suggested that the experience of jealousy is based on socially-learned expectations, in that people may believe that one event implies the existence of another event (DeSteno & Salovey, 1996). That is, although both types of infidelity should result in jealousy, the type that is most distressing to an individual would be the one that implies the occurrence of the other or, in other words, a "double-shot" of infidelity. DeSteno and Salovey (1996) proposed that the double-shot hypothesis explains sex differences in terms of the perceptions that infidelity of one type likely predicts that the other type of infidelity is also occurring (e.g. men may think that sexual infidelity is more distressing because they believe that if a woman has sex with another man, then she probably also is emotionally involved with him as well, and vice versa for women). Evidence has been mixed in terms of support for the double-shot hypothesis. Further investigation into more social explanations for the sex difference in jealousy was also conducted by DeSteno et al. (2002) who used a cognitive load manipulation which prevented the participants from reflecting on the types of infidelity. Under cognitive load, men's responses maintained greater distress to sexual infidelity. However, women's responses also shifted toward a stronger jealousy for sexual infidelity. The researchers contend that this finding potentially indicates that the sex difference in forced-choice studies may be caused by a self-presentation strategy by women.

Measures of Jealousy

Forced-choice format scales typically have participants choose which of two types of infidelity scenarios (emotional versus sexual) would cause them the most jealousy. This forced-choice method was first designed by Buss et al. (1992) and has since been used in numerous studies.

Non-forced choice response formats typically use continuous, Likert-type scales to assess jealousy experiences. (Checklist formats have also been less commonly used.) There are many examples of these scale types.

- Bringle, Roach, Andler, and Evenbeck's (1979) Self-Report Jealousy Scale (SRJS) is a unidimensional scale intended to measure dispositional characteristics of jealousy across all kinds of past relationships.
- Mathes and Severa's (1981) Interpersonal Jealousy Scale (IJS) is a 28-item scale measuring individual differences in jealousy.
- White's (1981) Relationship Jealousy Scale (RJS) is a 6-item, unidimensional scale that measures romantic jealousy.
- White's (1981) Chronic Jealousy Scale (CJS) is a 6-item, unidimensional scale that measures frequency and intensity of jealousy across previous and current relationships, romantic and non-romantic.
- Thissen, Steinberg, Pysczynski, and Greenberg's (1983) Romantic Jealousy Assessment (RJA) is made up of six hypothetical scenarios depicting situations which might lead a person to feel jealous.
- Pfeiffer and Wong's (1989) 24-item Multidimensional Jealousy Scale (MJS) is composed of three jealousy components: cognitive, emotional, and behavioral.
- Geary, Rumsey, Bow-Thomas, and Hoard (1995) had study participants imagine their own partners engaging in jealousy provoking behaviors and then how they would react.
- Guerrero, Andersen, Jorgensen, Spitzberg, and Eloy's (1995) Communicative Responses to Jealousy Scale (CRJS) is a 70-item scale measuring various communicative responses to jealousy.

Physiological measures of jealousy responses, such as electrodermal activity and pulse rate, have also been used. For instance, Buss et al. (1992) used measures of autonomic nervous system activity to assess jealousy reactions. They recorded physiological activation as people contemplated being victims of different kinds of infidelity. However, physiological measures have proven to be somewhat controversial.

Jealousy and Attachment

In his classic work, John Bowlby considered how childhood attachments to primary caretakers may serve as a working model for later adult relationships. Models of attachment are often composed of two basic dimensions, anxiety and avoidance (Brennan, Clark, & Shaver, 1998). Simpson and Rholes (1994) proposed that jealousy can also elicit these working models in romantic relationships. For instance, various researchers have proposed that people who are high in either avoidance or anxiety may experience increased jealousy.

Jealousy and Envy

The concepts of jealousy and envy are frequently compared in the research literature. Traditionally, envy occurs when a person lacks something of desire that another person possesses, or wishes that the other person did not have. Some researchers make a distinction between envy and jealousy, while others have failed to find qualitative differences. For instance, Salovey and Rodin (1986) concluded that the differences between jealousy and envy were more quantitative than qualitative, in that they produced similar affective experiences, but that jealousy was more intense. However, Parrott and Smith (1993) described qualitative differences between the two, in that envy was characterized by feelings of inferiority, longing, disapproval, and unsanctioned ill will, and jealousy was composed of fear of loss or rejection, anger, anxiety, and distrust.

Cross-cultural Comparisons

Various theorists have speculated that jealousy is more pronounced in cultures with an increased emphasis on the importance of marriage, for those cultures that approve of sex only within marriage, and for those cultures that highly value personal property (Harris, 2004). Evolutionary theorists contend that the evolutionary theory can account for jealousy across cultures, in that jealousy is adaptive and therefore universal. The evolutionary theory's pattern of findings has received cross-cultural support in samples from around the world, including China, the Netherlands, Germany, Korea, and Japan. Harris (2004) notes, however, that in comparison to samples from the United States, men from European or Asian countries are less likely to choose sexual infidelity as worse.

Cross-cultural research on sex differences in jealousy by Buunk and Hupka (1987) asked participants from seven nations (Hungary, Ireland, Mexico, the Netherlands, the Soviet Union, the United States, and Yugoslavia) how much they agreed with six jealousy-related statements regarding their partners. They found that men and women were similar for most of their responses, differing only on two of the six statements. Using both American and Chinese participants, Geary, Rumsey, Bow-Thomas, and Hoard (1995) found that in response to both emotional and sexual infidelity, American women reported more intense jealousy relative to American men, with a larger difference for emotional infidelity. Results were less consistent, however, for the Chinese sample, showing a small tendency for Chinese men, relative to Chinese women, to report more intense jealousy in response to sexual infidelity.

Love and Attraction, Assessment of

Stephanie B. Richman

Baldwin Wallace University

What Attracts People to Others

Attraction involves an individual's positive perception and evaluation of another person. As with any attitude, attraction has affective, behavioral, and cognitive components. That is, a person has positive feelings, behaviors toward, and thoughts about the person to whom they are attracted. The four major factors that influence whether a person is attracted to another are proximity, reciprocal liking, similarity, and physical attractiveness.

Proximity refers to the literal physical closeness of one person to another. That is, people are more likely to be attracted to those who live closer to them – in the same city or next door in an apartment complex. Many people can relate to the difficulty of maintaining a long-distance relationship, but not only are people less likely to maintain a pre-existing relationship in which a person does not live close by, so too are they less likely to start one. The reason this proximity effect works is because of a phenomenon known as the "mere exposure effect." The more often we encounter an object or a person, the more we like it. When people are physically closer to us, we will see them more frequently and thus we will like them more. We like others who we encounter more often.

Reciprocal liking refers to the intuitive notion that if a person is attracted to us, we will find them attractive. This effect works both on a general scale – people who tend to like others more in general are also liked more in general – as well as on a dyadic scale – people are more likely to like a particular person who likes them. We like others who like us.

Similarity refers to the fact that "birds of a feather flock together," rather than "opposites attract." The greatest predictor of attraction is similarity. These similarities can be in people's attitudes, beliefs, hobbies, and even their physical appearance or name. The phenomenon that people tend to become attracted to and start relationships with others who they are more similar to is known as assortative mating. The phenomenon shows that the most common characteristics for people to be similar to their spouses on include age, religiousness, and political orientation. There is a moderate similarity in education,

verbal intelligence, and values. Finally, there is the smallest amount of similarity in reasoning skills, personality, emotional experience, expression, and attachment style. We like others who are like us.

Finally, physical attractiveness is a robust predictor of whether or not we are attracted to someone. The first aspect about a person that we perceive is their physical attractiveness and it has a strong impact on our attraction toward them. The more physically attractive a person is, the more attracted others tend to be to them and the more likely they desire to be in a relationship with that person. People end up in relationships with someone who is comparable in attractiveness to themselves; they are unable to attract the most alluring targets unless they are equally as alluring. Although people may have idiosyncratic qualities about others that they find attractive (e.g. glasses versus no glasses, long hair versus short), there is widespread agreement about what the most physically attractive qualities are. Both men and women find others with a large smile, high set eyebrows, full lips, facial symmetry, and a confident posture as more attractive. Men specifically find women most attractive when they have prominent cheekbones, waist-to-hip ratios of approximately .70, and are shorter than them. Women specifically find men most attractive when they have a broad jaw, broad shoulders, and are taller than them. We like others who are physically attractive.

Measurements of Attractiveness

There are several methodologies used frequently by researchers to determine whether a person is attracted to someone else and the degree of their attractiveness. One commonly used paradigm involves non-conscious mimicry, that is the amount to which people unconsciously copy others' non-verbal behavior. People tend to mimic the behavior of others when they want others to like them and, similarly, people tend to like others better who mimic their behavior. Importantly, this effect is not one that people are consciously aware of, thus it is not due to self-presentation.

A relatively more novel method to measure attraction involves a recently popular procedure in the dating world: speed dating. In a typical speed dating event, women sit at small tables or in chairs around a room and men will rotate to meet all of the women exactly once. Each speed date lasts only a few minutes so each pair can briefly get to know each other. At the end of the session, each person indicates whether or not they would want to see the other person again. The organizers of the speed dating event will contact the pairs who "match" (who both say they would like to see the other person again). While speed dating originated as a dating event to allow single people to meet other singles, it is now also used in research to study attraction. Researchers manipulate or measure variables, like which gender is rotating and which is sitting or a person's self-confidence, and measure how that affects their attraction (i.e. who they said "yes" to).

Measurements of Love

For centuries people have been debating on the nature of love, how we should define it, and what it really means to love someone. Psychologists, also, have been debating on these same topics. The most popular model of love, taught in almost every introductory psychology

textbook, distinguishes three components of love: intimacy, or feelings of closeness to another person, commitment, or the decision to remain with another person over time, and passion, or sexual attraction for another person. One person's love for another can be measured using this model by determining how much of each type of love a person feels for someone. Two partners' models can even be compared to determine in what areas there might be a mismatch.

Love can also be measured biologically. People who are in love release more of the neurotransmitters oxytocin and dopamine. Oxytocin is associated with bonding, such as that which occurs between a mother and child or between two romantic partners. Dopamine is associated with feeling rewards and pleasure of any kind – eating a favorite food, engaging in a favorite activity, or spending time with a loved one. Love also has a specific pattern of neurological activation in the brain. Areas of the brain associated with the reward system and areas that contain receptors for oxytocin and dopamine are more activated in people who are experiencing romantic love. Additionally, areas of the brain associated with feeling negative emotions and with making social judgments are less activated in people who are experiencing romantic love. People who are in love are different on a biological and neurological level from those who are not.

There are also behavioral measurements of love. Self-expansion, or including attributes of another person into one's own sense of self, is one way that love is measured behaviorally. For example, becoming more artistic after starting a relationship with a person who is really artistic reflects a person self-expanding. The experience of falling in love involves self-expanding by taking on traits of the romantic partner and incorporating them into one's own sense of self. People literally become more like those that they love.

What Affects Love

Beliefs about love are a powerful moderating factor of a variety of indicators of relationship success. Some people believe that they have a "romantic destiny" or "soulmate," that is they feel it is their destiny to be with a specific individual; others believe that relationships are about growth and "working it out," that is they feel a relationship with anyone can be successful provided both parties work at it. These beliefs about love cause people to act differently in their relationships. People who believe in romantic destiny, compared to romantic growth, terminate relationships more quickly if they feel less satisfied initially in their relationship. Belief in romantic destiny is also related to coping strategies reflecting disengagement from one's partner and a lack of engaging in relationship maintenance following a negative relationship event. On the other hand, belief in romantic growth is associated with a more frequent use of maintenance strategies and generally dating a particular person for a longer period of time.

How people love is also strongly affected by their attachment style. Attachment style was first studied in the relationship between an infant and his or her primary caregiver. Infants with a secure attachment style have a positive relationship with their caregiver characterized by trust and positive emotions. Infants with an avoidant attachment style have a cautious relationship with their caregiver characterized by a suppressed desire to be close to them due to a fear of rejection. Finally infants with an anxious attachment style have an uneasy relationship with their caregiver, characterized by extreme distress, especially at the departure of the caregiver. Recently, attachment style has also been studied as an individual difference

variable and in adults in romantic relationships. People's relationship with their primary caregiver during childhood has an impact on their attachment to others, especially their romantic partner, later in life. Adult attachment is also characterized into secure, avoidant, and anxious and resembles the attachment styles of infancy. Securely attached people find it easy to get close to and depend on others. Avoidantly attached people are uncomfortable getting close to and depending on others. Finally, anxiously attached people are worried about being abandoned and find that others are reluctant to get as close to them as they want to be.

Masculinity and Femininity

Megan D. Shevenell and Elizabeth Harwood

Rivier University

Defining Gender

Gender differs from biological sex. Gender refers to the ideologies and behaviors of masculinity and femininity that individuals can learn to endorse and express, while biological sex refers to the genetic and hormonal markers that distinguish men from women. Biological sex is not an absolute determinant of gender. A biological man, classified at birth as a male, might display both feminine and masculine characteristics.

Theories of Gender Roles

Three prominent theories on the development of gender roles include social cognitive theory, gender schema theory, and social structure theory. Bussey and Bandura's (1999) social cognitive theory suggests that individuals learn gender from a young age through observation and modeling of behaviors from the adults in their lives and societal influences. Individuals enact these roles based on reinforcement from other people's reactions and responses, suggesting that gender is not static.

Bem's (1981a) gender schema theory indicates that gender roles remain stable once formed. Gender roles are schemas that help individuals organize information gained from exposure to behaviors, attitudes, and activities within the surrounding environment. A child might witness gendered appropriate behavior from their parents, teachers, and peers, which forms his/her internal ideas of gender.

Social structure theory, outlined by Risman (2004), suggests that gender roles are created and maintained by the traditional roles that men and women hold in society. Historically, men have provided for the family whereas women have been homemakers. Social structure theory asserts that gender is a result of these structural roles that society determines. Nurturing behavior results from women being placed in care-giving situations and

aggressiveness results from men being placed in the role of bread-winner. What are considered appropriate gender roles are subject to change as gender roles in society evolve.

Traits of Masculinity and Femininity

Based on the different theories of gender, masculine and feminine traits have been identified by Cowan and Warren (1994). The range of masculine behaviors includes independence, autonomy from others, concern with success, domination, lack of emotional expressiveness, and aggressiveness. The range of feminine behaviors includes emotional expressiveness, communion with others, intuition, servileness, nagging, and excessive worrying. The negative or positive connotation of these traits depends upon their social desirability. For example, communion with others is seen as a positive feminine trait as it helps to promote relationship building, while being too emotional may hurt relationship building and is considered a negative feminine trait. Masculine individuals are often driven to succeed, which is considered a positive masculine trait, as it propels the individual ahead in life. Aggressiveness, on the other hand, might be considered a negative masculine trait because it may hinder the ability to form relationships.

Social Desirability Bias

Social desirability bias is a concern with the self-report of gender roles and calls into question the validity of measures assessing these constructs. Many modern scholars theorize that masculinity is a construct which one can lose. Whereas women's femininity is not questioned after puberty, men who wish to be perceived as masculine must continually strive for masculinity. This is learned from a young age as little boys might be teased about "throwing like a girl" or told to "man up" if they are seen crying. In this sense, masculinity is something that must be earned or they risk being seen as feminine. Therefore, in modern gender role studies, men might skew their responses in such a way that they appear more masculine than they actually are. Though studies often provide confidentiality for their participants, this does not completely resolve the issue of social desirability bias.

The Importance of Gender Roles in Therapy

Even with issues in self-report, gender roles are important to assess as they may help inform clinical decisions. Masculinity and femininity have both been linked to negative psychological outcomes in individuals who strongly endorse one or the other. Individuals who identify as being very feminine often report more anxiety and depression (Muris, Meesters, & Knoops, 2005), whereas individuals who identify as being very masculine are more likely to abuse substances (Grief, 2009). Examination of gender roles might help inform both the client and therapist on the most appropriate method of treatment. For example, masculine individuals are usually not encouraged to talk about their feelings and may instead turn to substances as a way of coping with problems. In such an instance, an examination of gender might help the client and therapist better understand the current predicament and the client's resistance to traditional talk therapy.

Though extreme presentations of gender can impact individuals' clinical presentation in a negative way, gender role behaviors can also be beneficial. Some qualities associated with masculinity, such as autonomy, can actually help promote psychological adjustment (Adams & Sherer, 1982). Recognition of positive traits from both gender roles might help clinicians identify and emphasize these traits in their clients.

Assessment of Masculinity and Femininity

Two of the most widely used assessments for measuring masculinity and femininity are the Bem Sex Role Inventory (BSRI; Bem, 1981b) and the Personal Attributes Questionnaire (PAQ; Spence, Helmreich, & Stapp, 1974). The BRSI assesses masculinity and femininity on a continuum in an attempt to also capture the construct of androgyny. Individuals are scored on the degree to which they identify with both masculine and feminine characteristics. Androgynous individuals have scores that reflect both the average masculine and the average feminine individuals. Therefore, androgyny is not the absence of gender, but the balance of masculine and feminine characteristics.

The characteristics that define masculinity and femininity in the BSRI are based on personality traits that define current gender roles and are perceived as socially acceptable for members of each sex. These characteristics are rated on a unipolar 7-pt Likert scale (1 = almost never true to 7 = almost always true). Items on the femininity scale include being affectionate, conscientious, and helpful. Items on the masculinity scale include being self-reliant, independent, and assertive. The BSRI is considered reliable; the femininity scale has a coefficient alpha of .78, while the masculinity scale has a coefficient alpha of .87. The BSRI also has high test-retest reliability (Bem, 1981b).

The PAQ consists of three subscales: masculinity, femininity, and androgyny. The masculinity subscale, also known as the instrumentality subscale, contains personality traits that are typically ascribed to men, such as being independent, active, competitive, confident, and persistent. The femininity subscale, also known as the expressivity subscale, contains personality traits generally ascribed to women, such as being emotional, gentle, helpful to others, aware of others' feelings, and kind. The androgyny scale is not generally utilized in assessment, but contains items that include crying, having feelings hurt, and excitability in a crisis. The PAQ contains 24 items that are measured on a unipolar Likert scale from 1 = not at all to 5 = very to measure the degree to which individuals ascribe to the characteristic in question. The PAQ is considered reliable; the femininity scale has a coefficient alpha of .77, and the masculinity scale has a coefficient alpha of .80 (Helmreich, Spence, & Wilhelm, 1981).

The construct validity of these two questionnaires has been supported through factor analysis. Correlations between the two masculinity scales range from .72 to .84; the femininity scales share correlations ranging from .52 to .71 (Spence, 1991).

A newly developed instrument for assessing gender is the Traditional Masculinity-Femininity Scale (TMF; Kachel, Steffens, & Niedlich, 2016). The TMF specifically measures masculinity and femininity by assessing items regarding physical appearance, gender-related interests, and a self-assessment of attitudes and beliefs. The TMF is considered reliable, with a coefficient alpha of .94.

Comparing Gender Roles with Related Constructs

Masculinity and femininity have also been included in personality assessments. The Minnesota Multiphasic Personality Inventory (MMPI) is a personality test used to assess for psychopathology and other mental health concerns. The MMPI previously contained a clinical subscale, Scale 5, that specifically assessed for levels of masculinity and femininity (i.e. the Mf Masculinity-Femininity scale). The feminine items on this scale have been highly correlated with negative affectivity, anxiety, and depression, while the masculine items on this scale have been highly correlated with substance use and impulsivity. In fact, researchers Martin and Finn (2010) have speculated that this scale actually assesses for the latter, rather than true levels of masculinity or femininity.

The Mf scale has a weak correlation with the new scales for assessing gender on the MMPI-2; these supplementary scales are known as the GM/ Masculine Gender Role and the GF/ Feminine Gender Role scales. The GM scale assesses for the denial of weakness or psychological fears and for interests typically associated with masculinity (e.g. physical labor, science, adventure). The GF scale assesses for sexually repressive and emotional behaviors and for interests typically associated with femininity (e.g. romance, cooking, housework).

The PAQ and BSRI also have correlates with assessments measuring personality traits. On the PAQ, neuroticism has been highly correlated with the femininity subscale, while acting out has been highly correlated with the masculinity subscale (Spence & Helmreich, 1978). Similarly, the masculinity scale on the BSRI has been correlated with positive affectivity while the femininity scale has been correlated with constraint (Lubinski, Tellegen, & Butcher, 1981).

Cross-cultural Differences

Since masculinity and femininity are social constructs, gender roles may vary across cultures depending on the structure of society and what traits are valued. However, when examined cross-culturally, both the BSRI and PAQ have been shown to be reliable and valid measures of masculinity and femininity (Moneta, 2010; Wilson, McMaster, Greenspan, Mboyi, Ncube, & Sibanda, 1990).

Next Steps

Due to the changing nature of men and women's roles in society, it is likely that the assessment of the typically ascribed gender roles will also have to evolve. Most of the current methods used for assessing masculinity and femininity are based on societal norms and may eventually become obsolete or reassessed as culture and society continue to change.

Narcissism, Assessment of

Laura K. Johnson and Hiten P. Dave

Western University

Narcissism Defined

In empirical psychology, narcissism is conceptualized as a clinical personality disorder, as well as a subclinical personality trait (trait narcissism). Narcissism is characterized by egotism, grandiosity, dominance, and self-enhancement (Raskin & Hall, 1979). Individuals high in narcissism ("narcissists") feel entitled to special treatment because they perceive themselves as better than others. They attempt to maintain this self-image through eliciting admiration. Similarly, narcissists are sensitive to criticism and react aggressively to perceived threats to their self-image. In interpersonal situations, narcissists make good first impressions, often seen as charming, attractive, and assertive in short-term relationships (Back, Schmukle, & Egloff, 2010). However, these initial positive impressions degrade over time as more antagonistic elements of narcissism become apparent. Pathological narcissism is known as Narcissistic Personality Disorder (NPD) (see Narcissistic Personality Disorder) in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) (see DSM-V), and is typically diagnosed by a clinician. While it has similarities with trait narcissism, NPD is highlighted by great distress and impaired social functioning.

Subtypes

Narcissism can be divided into two subtypes: grandiose narcissism and vulnerable narcissism (Miller et al., 2011). While these subtypes are both associated with the exploitation of others, low empathy, and aggression, they have different nomological networks. Grandiose narcissism is characterized by feelings of superiority, entitlement, a need for admiration, and self-enhancement strategies. In contrast, vulnerable narcissism is characterized by low self-worth, desire for praise, hypersensitivity to perceived criticism, and beliefs that others have malevolent intentions toward them (*hostile attribution bias*). Despite some overlap, it

is currently unclear if the subtypes are mutually exclusive, or different dimensions of a continuous trait (Miller et al., 2011).

Related Constructs

Self-esteem

A common misconception of narcissism is that it results from excessive self-esteem (see Self-esteem, Theory of), or sense of self-worth. Indeed, both narcissism and self-esteem involve thinking positively about oneself. However, differences between these constructs suggest that narcissism is not the result of inflated self-esteem. Empirically, narcissism and self-esteem are only modestly correlated (Campbell, Rudich, & Sedikides, 2002). Highly narcissistic individuals are defensive, perceive themselves as superior to others, and demand praise. In contrast, individuals with high self-esteem do not necessarily compare themselves to others or display the antagonistic behaviors that encompass high trait narcissism (Brummelmann, Thomaes, & Sedikides, 2016).

Egotism

Egotism and narcissism are often used interchangeably. Although narcissism and egotism are strongly correlated (Veselka, Schermer, & Vernon, 2011), they are distinct constructs. Egotism reflects excessive self-interest, sense of superiority, and sense of self-importance (Campbell, Bonacci, Shelton, Exline, & Bushman, 2004). However, egotism lacks the antagonistic, aggressive reaction to criticism associated with narcissism. Instead, it is characterized by a need for self-enhancement. As such, egotism is better conceptualized as a component of narcissism, rather than an identical construct.

Theoretical Views

Narcissism within the Dark Triad

Subclinical narcissism, Machiavellianism and subclinical psychopathy form the "Dark Triad" (see Dark Triad) of personality (Paulhus & Williams, 2002). These traits involve social malevolence, exploitation of others, and low empathy. Narcissism is regarded as the "lightest," or least socially malevolent of the traits. In fact, aspects of narcissism (e.g. boldness, assertiveness, charm) may be perceived favorably in certain contexts (Rauthmann & Kolar, 2012). Measures of the Dark Triad include narcissism subscales; however, because these subscales are unidimensional and very brief, they do not necessarily capture all of the facets of narcissism.

Narcissistic Admiration and Rivalry Concept (NARC)

According to the NARC model, narcissism includes both assertive and antagonistic dimensions. In this model, Back et al. (2013) propose that narcissists employ two social strategies

to maintain their grandiose self-image: assertive self-enhancement (*narcissistic admiration*) and antagonistic self-protection (*narcissistic rivalry*). Narcissistic admiration involves grandiose fantasies (e.g. beliefs that they are influential or superior), striving for uniqueness, and seeking admiration. This, in turn, promotes popularity and other positive social outcomes. In contrast, narcissistic rivalry involves striving for superiority, degrading others, and responding aggressively to ego threats (e.g. anger and hostility in response to criticism). While this behavior protects against failure and rejection, it also promotes social conflict (i.e. antagonizing others).

Overview of the Measures

While several measures of narcissism have been proposed, two scales are the most prominent in the literature: the Narcissistic Personality Inventory (NPI; Raskin & Hall, 1979) and the Narcissistic Admiration and Rivalry Questionnaire (NARQ; Back et al., 2013). Measures of egotism and entitlement have also been developed, of which the Psychological Entitlement Scale (PES; Campbell et al., 2004) is the most widely used.

Narcissistic Personality Inventory

The NPI is the most popular measure of narcissism. It is a 40-item forced-choice scale with items based on the DSM criteria for NPD, adapted for assessment in the general population. However, researchers cannot agree on its factor structure. Using principal-components analysis, Raskin and Terry (1988) reported seven components of the NPI: Authority, Superiority, Exhibitionism, Entitlement, Vanity, Exploitativeness, and Self-sufficiency. Meanwhile, other researchers have found two to four factors for the NPI, though two- or three-factor solutions are the most commonly reported, generally reflecting Leadership/Authority (e.g. "People always seem to recognize my authority."), Entitlement/Exploitativeness (e.g. "I find it easy to manipulate people.") and Grandiose Exhibitionism (e.g. "I really like to be the center of attention"; Ackerman et al., 2011).

While users of the NPI traditionally rely on a total score, its factors have been linked to distinct outcomes. For example, Ackerman et al. (2011) linked their Leadership/Authority factor to adaptive outcomes (such as higher self-esteem), and their Entitlement/Exploitativeness factor to maladaptive outcomes (such as social toxicity). Because of these different nomological networks, some researchers recommend considering facets of narcissism in addition to total scores when assessing narcissism.

Additionally, shorter versions of the NPI have been developed for speedier administration: the NPI-16 (Ames, Rose, & Anderson, 2006) and the NPI-13 (Gentile et al., 2013). The key difference between these scales is that the NPI-16 is unidimensional, whereas the NPI-13 has three subscales (Leadership/Authority, Grandiose Exhibitionism, Entitlement/Exploitativeness), which parallels Ackerman et al.'s (2011) three-factor structure. All three measures have similar relationships with the Big Five (see Big Five) personality traits (i.e. negative correlations with Agreeableness and Neuroticism; positive correlations with Extraversion), as well as positive correlations with psychopathy (see Psychopathy) and aggression (Gentile et al., 2013).

Narcissistic Admiration and Rivalry Questionnaire

The NARQ is an 18-item measure of grandiose narcissism that assesses two dimensions: Admiration and Rivalry. These two factors, while correlated, reflect two distinct social strategies by which narcissists can maintain a grandiose self-image. Admiration reflects the self-promotion component of narcissism, whereas Rivalry reflects a strategy of antagonistic self-defense against social rejection. Each subscale has a total of nine items, which are scored on a 6-point Likert-type scale, and three facets. The facets of Admiration are grandiosity (e.g. "I am great."), uniqueness (e.g. "I show others how special I am."), and charmingness (e.g. "I manage to be the center of attention with my outstanding contributions."). The facets of Rivalry are devaluation (e.g. "Most people won't achieve anything."), striving for supremacy (e.g. "I want my rivals to fail."), and aggressiveness (e.g. "I often get annoyed when I am criticized."). Both the Admiration and Rivalry dimensions have demonstrated high internal consistency (Admiration: α = .88, Rivalry: α = .83; Back et al., 2013).

While both subscales converge with the NPI, they have different relationships with other traits and predict different behavioral outcomes. Additionally, the Rivalry dimension focuses on the more antagonistic elements of narcissism, which are less represented in the NPI. Admiration roughly maps onto the Leadership/Authority factor of the NPI, whereas Rivalry roughly corresponds to the Entitlement/Exploitativeness factor. Both dimensions of the NARQ are positively linked to pathological narcissism, entitlement, and psychopathy. However, Admiration is positively linked with self-esteem and neuroticism, whereas Rivalry is inversely related to self-esteem and neuroticism (Back et al., 2013). Based on these relationships, it is evident that the NARQ balances both adaptive and maladaptive elements, whereas the NPI focuses on the more assertive elements of narcissism. While both measures have shown non-trivial amounts of overlap, the NARQ has stronger unique associations with the Big Five traits compared to the NPI (Back et al., 2013).

Psychological Entitlement Scale

The PES is a nine-item measure of entitlement, or the extent to which an individual feels more deserving of respect and privilege than others (Campbell et al., 2004). Items are measured on a 7-point Likert-type scale (e.g. "I demand the best because I'm worth it."). The scale has demonstrated high internal consistency (α = .86 – .88; Campbell et al., 2004). The scale is unidimensional and demonstrates convergent validity with the NPI, both overall and with the seven factors reported by Raskin and Terry (1988). Entitlement has been reported to have negative correlations with Agreeableness ($r = -.19$) and Emotional Stability ($r = -.16$) of the Big Five personality traits, as well as with empathy ($r = -.16$) (Campbell et al., 2004). Although egotism and entitlement are not identical constructs to narcissism, they are key components of this trait. As such, the PES can be used to complement measures of narcissism, or on its own to measure individual differences in entitlement.

Optimism/Pessimism, Assessment of

Scott P. King and Jacob Belkin

Shenandoah University

Overview

Optimism, broadly defined, is one's tendency to expect positive outcomes, whereas pessimism is one's tendency to expect negative outcomes. A large body of research points to positive relationships between optimism and both psychological and physical health. Originally measured as a unidimensional construct (with optimism and pessimism at opposite poles) with the Life Orientation Test by Michael Scheier and Charles Carver in 1985 (see Optimism/Pessimism Carver and Scheier Theory), most modern research views optimism and pessimism as two separate but related constructs. Personality researchers have operationalized optimism and pessimism from both global and domain-specific perspectives. Assessments of these constructs, therefore, tend to follow the theoretical perspectives of their authors, based on how many dimensions are present in optimism-pessimism and whether it is being measured as a general trait or relating to a specific area. This entry includes descriptions of commonly used assessments of optimism-pessimism, all of which have been shown to have adequate internal consistency. Given that all the assessments are self-report and most validity data come from university student samples, however, work remains to be done to support construct and external validity of some.

Global Unidimensional Assessments

The *Life Orientation Test* (LOT, 1985), published by Scheier and Carver and revised in 1994 (LOT-R), was designed to assess dispositional optimism, a stable trait reflecting a belief that more good things will happen in one's life compared to bad things, based on the idea that optimism and pessimism were two ends of a single construct. Although numerous other models and measures have been developed, these instruments are the most widely used.

The LOT includes 12 items answered in a five-point (0 = strongly disagree, 4 = strongly agree) format. Four items measure optimism; four items measure pessimism, and four filler items are unscored. Higher scale scores indicate more optimism.

The LOT-R is a modification of the LOT that omits two LOT items thought to reflect coping strategies instead of positive expectations, adds a new optimism item, and omits a pessimism item, resulting in a 10-item scale. Three items measure optimism; three items measure pessimism, and four items are unscored. Higher scale scores indicate more optimism.

While still global and unidimensional, numerous indirect assessments of optimism-pessimism are rooted in Martin Seligman and colleagues' attributional style theory, where a person can have either an optimistic (good events happen because of internal, stable, and global factors; negative events happen because of external, unstable, and specific factors) or pessimistic (opposite of optimistic) explanatory style. Popular assessments of optimism and pessimism from this perspective include Christopher Peterson and colleagues' *Attributional Style Questionnaire* (ASQ, 1982), and *Expanded Attributional Style Questionnaire* (EASQ, 1988), and Robert Colligan and colleagues' *Optimism-Pessimism Scale for MMPI* (PSM, 1994) and *Revised Optimism-Pessimism Scale for MMPI and MMPI-2* (PSM-R, 1995).

The ASQ presents respondents with six good (e.g. "You do a project that is highly praised") and six bad (e.g. "You go out on a date and it goes badly") hypothetical events, and asks them to write a major cause of each event in their own words. Respondents then rate that cause on each of three attributional dimensions (its internality, stability, and globality) on seven-point scales. Composite scores are created for each event, with higher scores for positive events indicating more of an optimistic explanatory style, and higher scores for negative events indicating more of a pessimistic explanatory style.

The EASQ expands on the ASQ by including 24 negative events and omitting any positive events, in order to improve upon the modest reliability of the ASQ. Higher scores indicate more of a pessimistic explanatory style.

The PSM and PSM-R are assessments of optimistic and pessimistic explanatory style based on applying Peterson and Seligman's *Content Analysis of Verbatim Explanations* (CAVE) technique to responses from the Minnesota Multiphasic Personality Inventory (see Minnesota Multiphasic Personality Inventory (MMPI)). The PSM consists of 298 true-false items from the MMPI identified with the CAVE technique as reflecting one's explanatory style, with higher scores indicating a more pessimistic explanatory style. The PSM-R consists of 263 items appearing on both the MMPI and MMPI-2, again with higher scores indicating a more pessimistic explanatory style.

Global Multidimensional Assessments

Several assessments have been developed based on the conceptualization of general optimism-pessimism as at least two related constructs, with empirical support that people can have separate but related levels of both optimism and pessimism. Most of the assessments below focus on optimism and pessimism.

The *Optimism and Pessimism Scale* (OPS, 1989), designed by William Dember and colleagues to measure optimism and pessimism as two poles of a single trait, ended up (after their psychometric analyses) being the first scale to separate optimism and pessimism as related subtraits rather than a unidimensional trait. The OPS includes 56 items answered in a 4-point (1 = strongly agree, 4 = strongly disagree) format. Eighteen items measure optimism; 18 items measure pessimism, and 20 items are unscored. The scale provides subscale scores for each optimism and pessimism subtraits, with higher scores indicating more of the construct.

The *Extended Life Orientation Test* (ELOT, 1997) was created by Edward Chang and colleagues as a mix of seven LOT and eight OPS items with the purpose of supporting earlier research pointing to the bidimensionality of optimism and pessimism. The 20-item ELOT uses the LOT's answer format, and includes six optimism items, nine pessimism items, and five unscored items, with higher scores in each subscale indicating more of the construct.

The *Positive and Negative Expectancy Questionnaire* (PANEQ, 2001), created by Daniel Olason and Derek Roger, measures optimism, pessimism, and "fighting spirit," and acknowledges substantial overlap between positive/negative affect (see Positive and Negative Affective States, Assessment of) and optimism/pessimism, respectively. The 48-item instrument includes 10 Positive Affect/Optimism subscale items, 23 Negative Affect/Pessimism subscale items, and 15 Fighting Spirit subscale items, all answered in four-point (1 = strongly disagree, 4 = strongly agree) format, with higher scores on each subscale reflecting more of the construct.

The *Assessment of Personal Optimism and Social Optimism-Extended* (POSO-E, 2001), from Karl Schweizer and colleagues, provides a broader view of optimism, including social optimism (expecting positive outcomes in social/environmental domains), personal optimism (expecting positive outcomes in personal domains) and self-efficacy optimism (expecting that one's abilities will result in positive outcomes). The 44-item instrument includes 26 social optimism items, 8 personal optimism items, and 10 self-efficacy optimism items, all answered in a four-point (1 = incorrect, 4 = completely correct) format, with higher subscale scores indicating more of the construct.

The *Optimism-Pessimism-2 Scale* (SOP2, 2013), from Kemper and colleagues, is a unique bidimensional assessment of optimism and pessimism, in that it consists of only two items (one measuring optimism and one measuring pessimism). Each item provides a definition of the construct, then asks participants to evaluate on a seven-point (1 = not at all optimistic/pessimistic, 7 = very optimistic/pessimistic) scale how optimistic/pessimistic they are.

Domain-Specific Assessments

With the emergence of positive psychology, research on the relationship between optimism and health/well-being variables has increased substantially since the 1980s. Development of domain-specific assessments of optimism-pessimism has grown as well, including several measures of specific types and context-focused optimism-pessimism.

Unrealistic optimism (one's belief that disproportionately more good things than bad will happen to one's self) and *comparative optimism* (the belief that one will experience more good things than comparable others) are both related to positive self-enhancement biases. These constructs have been typically measured directly (e.g. "Compared to the typical person, what is the chance that ___ will happen to you?") and indirectly, where people assess their own chances of an event happening to them, and then the chances of that event happening to the "average" person.

Defensive pessimism refers to a domain-specific cognitive strategy in which people set low expectations for their performance in a future event, in order to cushion the impact of potential failure. Two scales created by Julie Norem, Nancy Cantor, and colleagues classify respondents as users of defensive pessimism, strategic optimism (its converse), or aschematic (neither strategy) in a given domain.

The *Optimism – Pessimism Prescreening Questionnaire* (OPPQ, 1986) classifies users of the above strategies in academic domains via a nine-item (four optimistic items, four pessimistic items, one selection item) questionnaire in an 11-point (1 = not at all true of me, 11 = very true of me) answer format, with lower scores indicating greater likelihood of using defensive pessimism.

The *Defensive Pessimism Questionnaire* (DPQ, 1993) works similarly, but allows for tailoring to a variety of domains. It includes 17 items answered in a seven-point (1 = not at all true of me, 7 = very true of me) format, producing total scores as well as subscale scores for pessimism and reflectivity (how much users think about possible outcomes of an event), with higher scores indicating greater use of that strategy in a given domain.

Given the large amount of research on the relationship between optimism and health outcomes, numerous optimism assessments meant for use in specific populations have been developed as well.

One such scale, the *HIV Treatment Optimism Scale* (HIV-TOS, 2000), created by Paul van de Ven and colleagues, measures optimism about HIV treatment programs. Intended for use among gay men, it includes 12 items answered in a four-point (1 = strongly disagree, 4 = strongly agree) format assessing the degree to which respondents are optimistic about the likelihood and treatment of HIV infection, with higher scores indicating more optimism.

Another example, the *Cancer Patient Optimism Scale* (CPOS, 2005), developed by Laurel Radwin and colleagues, measures optimism among cancer patients regarding their treatment choices and prognoses. It includes four items answered in a six-point format (1 = never, 6 = always) format, with higher scores indicating more optimism.

Affect Defined

Valence is typically viewed as a defining feature of affect, characterized by positive or negative individual responses that reflect either transient, "in the moment" responses (*state affect*) or relatively stable individual differences *(trait affect)*. Whereas state affect reflects how one *currently* feels, trait affect reflects how one *generally* feels. Arousal is another important component of affect, which reflects how activated or intensely one feels. While the earliest theories of emotion focused extensively on physiological responses, later theories actively incorporated both valence and arousal.

Affect researchers also differentiate moods and emotions, which vary by duration, intensity, and cause. Moods tend to be long lasting, diffuse, and not linked to any specific cause (i.e. a particular object or event). In contrast, emotions, such as anger, joy, and sadness, are more differentiated, tend to be more intense, of shorter duration, and are often felt in response to a specific eliciting object or event.

Self-Report Measures of Affect

Self-report measures of affect are the most commonly used and the easiest way to assess affect. Such measures reflect differences in theoretical approaches and in the underlying structure of affect. Research in the 1960s and 1970s focused extensively on discrete models of affect, typically assessing *specific* moods and emotions, such as anxiety, depression, and hostility. Two measures that have been widely used include Marvin Zuckerman and Bernard Lubin's (1965) Multiple Affect Adjective Check List (MAACL), described in their *Manual for the Multiple Affect Adjective Check List*, and Douglas McNair, Maurice Lorr, and Leo Droppleman's (1971) Profile of Mood States (POMS), described in their *Manual: Profile of Mood States*. These scales require individuals to indicate whether specific adjectives

describe their current, past, or general affect, and therefore, have been used to capture both state and trait affect. These measures reveal a similar basic set of affective experiences, including anger, fear, sadness, anxiety, and happiness; however, one significant limitation of these measures is that the specific scales demonstrate poor discriminant validity. That is, the various negative affect scales are typically highly correlated, revealing that people tend to experience negative emotions, such as sadness and anxiety, together. Such findings led researchers to develop hierarchical models of affect to capture *general* dimensions of affect. Two prominent models exist, each of which identifies two separate dimensions of affective experience. One model focuses on valence and arousal as the key dimensions, whereas the other focuses on positive and negative valence.

Valence and Arousal Dimensions

According to one influential model advanced by James Russell in his 1980 article, "A Circumplex Model of Affect," affective experiences vary in the extent to which they are *pleasant versus unpleasant* (i.e. the degree to which one feels good versus bad) and *activating or arousing* (i.e. the degree to which one feels energized and engaged versus sleepy and tired). Affective experiences (i.e. pleasure, excitement, arousal, distress, displeasure, depression, sleepiness, and relaxation) are spatially arranged in a circle that is organized by these two key orthogonal (i.e. independent) bipolar dimensions. Fear and sadness, for example, are both negatively valanced, but fear is high in arousal, whereas sadness is low in arousal. In this model, higher positive feelings are theoretically associated with lower negative feelings (i.e. positive and negative affect are inversely correlated), and higher feelings of arousal are associated with lower feelings of sleepiness. Although early identification of these dimensions emerged from investigations of individuals' lay understanding of how affective states relate to one another, James Russell was among the first to demonstrate that self-reported emotional experiences reflect this underlying structure. He initially did so by asking participants to indicate how accurately each of a series of adjectives representing the different areas of the circumplex described how they felt that day.

In 1989, James Russell, Anna Weiss, and Gerald Mendelsohn introduced the Affect Grid in their article, "Affect Grid: A single-item scale of pleasure and arousal." This measure was designed to be brief and easy to administer, and therefore could be used for continuous and repeated measurement of affect within individuals. The Affect Grid reflects the two dimensions of high versus low arousal and unpleasant versus pleasant feelings, each of which is represented by 9 boxes, producing a 9 × 9 grid. Participants place a checkmark in one of the 81 boxes to reflect how they are feeling. The Affect Grid demonstrates adequate convergent and discriminant validity with other measures of pleasure and arousal, but as a single-item measure, it is less reliable than longer scales. In addition, it does not provide information about discrete affective experiences. When time allows, longer scales are recommended for measuring affect.

Positive and Negative Valence Dimensions

In contrast to the Circumplex Model, a different approach rests on a bivariate model of affect and maintains that affective valence is not one bipolar dimension, but rather is captured by two independent dimensions reflecting positive and negative affect. According to

this model, positive and negative affect are not inversely correlated, but vary independently. Further, arousal is not separate from valence; it is assumed that as positive and negative affect increase, arousal also increases.

The most widely used self-report measure based on this approach is the Positive and Negative Affect Schedule (PANAS) developed by David Watson, Lee Anna Clark, and Auke Tellegen, and described in their 1988 article, "Development and validation of brief measures of positive and negative affect: The PANAS Scale." This measure requires respondents to indicate the extent to which they feel 10 positive affective states (active, alert, attentive, determined, enthusiastic, excited, inspired, interested, proud, strong) and 10 negative affective states (afraid, ashamed, distressed, guilty, hostile, irritable, jittery, nervous, scared, upset) using scales that range from 1 (*very slightly or not at all*) to 5 (*extremely*). Using the PANAS, one can assess different types of affective experiences (e.g. state versus trait) by asking participants to report their affect during different time frames, such as right now, today, the past few days, the past week, past few weeks, past year, and in general (i.e. on average).

Factor analyses utilizing orthogonal rotation (which constrains factors to be uncorrelated) consistently reveal separate positive and negative affect factors regardless of the time frame in which affect is being assessed. The PANAS has demonstrated high internal consistency reliability, high stability when measuring affect in long-term intervals (e.g. past year, in general), and expected fluctuations when measuring changes in affect that occur in the short term (e.g. right now, today). Significant evidence also reveals that the scales demonstrate convergent and discriminant validity. The PANAS has been translated into multiple languages and been used in many different countries, revealing the two-factor positive and negative affect structure described here, regardless of language or culture. The scale has also been used with both non-clinical and clinical populations. Thus, this scale is a highly reliable and valid way to assess positive and negative affect; however, it is not without criticisms.

Some researchers argue that several terms included in the scales are not clearly emotions, such as strong, active, and alert. While true, this does not diminish the value of the PANAS in differentiating positive and negative experiences. Others note that only high activation affect is included in the PANAS; low activation positive (e.g. serenity) and negative (e.g. fatigue) affective experiences are absent. Thus, some maintain that this accounts for the emergence of unipolar positive and negative affect dimensions. Subsequent research has demonstrated that adding low activation affect did not improve the psychometric properties of the scales, and sometimes these additions reduced the reliability and validity of the measure. Thus, despite some criticisms, the PANAS captures important underlying dimensions of affect and has performed well at predicting a wide range of important individual variables and outcomes. The PANAS continues to be very widely used in psychology and in many applied disciplines.

To demonstrate the hierarchical structure of affect and to assess lower level, more discrete affective experiences as well as the higher-order positive and negative affective dimensions tapped by the PANAS, David Watson and Lee Anna Clark developed a 60-item expanded version of the PANAS. This scale is described in their 1994 manual, *The PANAS-X: Manual for Positive and Negative Affect Schedule-Expanded Form.* The PANAS-X includes the 20 items from the original PANAS, as well as scales to assess 11 specific affective

experiences (i.e. fear, sadness, guilt, hostility, shyness, fatigue, surprise, joviality, self-assurance, attentiveness, and serenity). Thus, the PANAS-X allows for affect to be measured at two different levels of specificity. Based on factor analyses, Watson and Clark grouped the lower-order scales into three broad categories: *Basic Negative Emotion Scales* (fear, sadness, guilt, hostility), *Basic Positive Emotion Scales* (joviality, self-assurance, attentiveness), and *Other Affective States* (shyness, fatigue, surprise, serenity). The Basic Negative Emotion Scales are significantly intercorrelated and compose a higher-order negative affect factor. Likewise, the Basic Positive Emotion Scales are intercorrelated and form a higher-order positive affect factor. The remaining scales do not clearly and consistently load on either factor. Depending on researchers' interests, the various lower-order scales may be used to assess discrete affective states. Overall, the PANAS-X scale is a reliable and valid measure of positive and negative affect, though researchers have used it much less frequently than the PANAS.

Other Measures of Affect

Great efforts have been expended to identify measures of affect that do not rely on self-report, specifically physiological and neurological measures. These measures, along with many other self-report measures, can be reviewed in *The Handbook of Emotion Elicitation and Assessment*, a comprehensive volume edited by James Coan and John Allen (2007). The future of affect assessment may well lie in the development of non-self-report measures, which have the advantage of assessing affective markers without a perceiver's conscious awareness. Such measures reduce concerns that are inherent in many self-report measures (e.g. self-presentation, clarity of and access to knowledge about oneself). For example, implicit assessments of affect have recently emerged, such as the one developed by Markus Quirin, Miguel Kazén, and Julius Kuhl, and described in their 2009 article, "When nonsense sounds happy or helpless: The Implicit Positive and Negative Affect Test (IPANAT)." This brief measure assesses affective states by asking participants to rate the extent to which words derived from an artificial language (e.g. SAFME) sound like different affective adjectives (i.e. happy, helpless, energetic, tense, cheerful, inhibited). Though a relatively new measure, the IPANAT has so far demonstrated adequate reliability and validity for measuring both state and trait affect. As evidence using this measure and others accumulates, affect scholars will be better able to determine the extent to which the measures have widespread utility and value.

Self-Esteem, Assessment of

Elvis W. DeFreese and Gerald E. Nissley

East Texas Baptist University

William James conceptualized self-esteem as being the degree to which people view themselves based on their accomplishments. Furthermore, these accomplishments are viewed through the lenses of the individual's goals and dreams. Since James' original conception of self-esteem, there have been numerous definitions, terms, perspectives, and positions taken or related to this term. Many counselors and other mental health professionals believe they know what self-esteem is, but most of those are unable to give a precise definition of self-esteem. Many of the attributes that are associated with self-esteem are the same as the self-concept construct, and the primary attribute happens to be one's attitudes toward the self. Self-esteem has been defined as the feelings of worth and acceptance toward the self based on one's own judgments of self. These judgments are derived from achievements, external sources, and as a consequence of one's awareness of competence. Morris Rosenberg has been one of the primary theorists to contribute to the understanding and measuring of self-esteem. Rosenberg believed that self-esteem included feelings of self-respect, self-liking, and self-acceptance. These aspects of self-esteem from Rosenberg's perspective have been applied to both the understanding of specific self-esteem and the understanding of global self-esteem. Global self-esteem deals with an individual's feelings toward the self as a whole, but specific self-esteem is how the individual feels about themselves in particular areas or aspects of their life, such as physical appearance, competency in career and academic areas, and social competence.

One of the most common confusions or misconceptions about self-esteem is that the term *self-esteem* can be interchangeably used with narcissism. However, the majority of the research has found that high or healthy self-esteem is more closely related to traits surrounding humility than it relates to traits of narcissism. Individuals with high self-esteem like themselves and accept themselves, but they do not typically participate in the exploitive, entitled, and grandiose behaviors of someone who is narcissistic. Self-esteem has been found to remain consistent throughout the lifespan of an individual. In other words, a person's self-esteem is set at a default of either positive (high) or negative (low), and though the degree may fluctuate throughout their lifetime their self-esteem typically reverts back to its default.

The function of self-esteem can be understood from three different perspectives: the cultural norm-fulfillment perspective, the interpersonal-belonging perspective, and the getting-ahead perspective. These three perspectives have been used to make contrasting predictions in relating the Big Five personality traits (Extraversion, Agreeableness, Neuroticism, Conscientiousness, and Openness to experience) with self-esteem. Some define self-esteem as the degree to which individuals live up to cultural norms, included with other people, and getting along in the social world. Rosenberg believed that once a cultural normative trait became important to a person, it would begin to impact the global self-esteem level of the individual rather than remain on the specific self-esteem level. Cooley found early on that self-esteem was largely impacted by interpersonal belongingness. This is where self-esteem and varying attachment theories from Bowlby, Reis, Baumeister & Leary, Hazan & Shaver, and Tajfel & Turner become intertwined. The getting-ahead perspective views interpersonal belonging as a way to reduce anxiety and to maintain one's own self-esteem.

Counselors, clinicians, and researchers have several options for assessing self-esteem levels. They can use self-report, behavioral observations, ratings from others, and interview methods. Self-esteem measurements come from a variety of theoretical backgrounds including behavioral and cognitive. Assessments have been developed to measure the self-esteem of both adults and children, and while some assessments have been found useful in some cross-cultural studies, most of them have been culturally biased. Most measures have been found to be unbiased as far as gender is concerned. The current adult measures consist of the Rosenberg Self-Esteem Scale (RSES) and the Janis-Field Feeling of Inadequacy Scale. The RSES incorporates questionnaires into research on self-esteem, and the RSES contains questions about 10 different items, and the responses are evaluated based on a four-point scale. While the RSES has been found to be very useful within the United States and other English-speaking countries, it is not as effective or useful in assessing the self-esteem levels of participants from other countries and cultures. The Janis-Field Feeling of Inadequacy Scale was developed from the view that self-esteem is essentially how comfortable a person feels in their social relationships. The scale measures a person's anxiety in social situations, self-consciousness, and feelings of personal worthlessness. Questions pertaining to 23 different items are used and evaluated based on a 5-point scale.

The current self-esteem measures for children consist of the Coopersmith Self-Esteem Inventory, the Pope's 5-Scale Test of Self-Esteem, and the Kid-KINDL. There has also been an adaptation to the Rosenberg Self-Esteem Scale so that it can be used with children. The Coopersmith Self-Esteem Inventory was developed based on the belief that self-esteem has to do with the expression of approval or disapproval of oneself, the extent to which one believes that they are talented or successful or that their lives have meaning and value. Coopersmith developed 58 evaluation criteria for children and 50 for adults. This scale requires participants to answer with either "Like me" or "Unlike me." Additionally, Coopersmith believed that a healthy self-esteem could be formed through parental warmth and acceptance, defined and enforced boundaries, and respect for action within those limits. The Pope's 5-Scale Test for Self-Esteem for children was developed with the basis that self-esteem is the evaluative feelings a person holds of themselves and the sense of worth that one has. Additionally, the developers of the scale believed that self-esteem, when evaluated, is the difference between the real self and the ideal self. According to this scale,

self-esteem is high when the real self and the ideal self are in agreement, and self-esteem is low when there are discrepancies between the two. This scale contains 60 questions and 5 subscales: Global Scale, Academic Scale, Body Scale, Family Scale, and Social Scale. The highest score possible is 20 and each subscale is used in the evaluation. A Lie Scale was also developed to evaluate response validity on this test. The Kid-KINDL was developed by Ravens and Bullinger and is used as an indicator of the quality of life in children. The developers defined quality of life as the subjective perception physical, mental, social, and functional aspects of well-being and health. The Kid-KINDL is meant for use with children between the ages of 6 and 18 years of age. The measure includes 24 questions regarding six areas: physical health, emotional well-being, self-esteem, family, friends, and school. The composite score of all these areas gives the quality of life score, and a high score in quality of life is interpreted as one having high self-esteem.

There are several more measures used for assessing self-esteem, but they have been designed for a general population rather than for specific demographics such as age, race, or gender. For example, there are three projective measures for assessing self-esteem while there are others that assess self-esteem from the cognitive and behavioral models. Most of these measures are self-report, but there are some which use observational reports rather than self-report. The projective tests include the Ziller Social Self-Esteem Scale, the Implicit Association Test (IAT), and the Implicit Relational Assessment Procedure (IRAP). The Ziller Social Self-Esteem Scale is a measure that uses topological representations of self and others in order to evaluate the individual's perception of their worth within the context of a self-other orientation. This measure uses very few verbal demands. The scale uses six different items pertaining to the self while using five different categories meant to describe your relationship with significant others. The IAT is an examination of an individual's latent attitudes toward the self. It is a computerized test where stimulus words appear on a screen and the participant responds to the word by striking one of two keys. One key is associated with positive feelings toward the word and the other key is associated with negative feelings toward the word or what it represents. Self-esteem is measured by the response time or the time it takes for the person to give their answer. There have been studies performed that used an implicit measure to differentiate between the actual self- and the ideal self-esteem. The results implicated that actual versus ideal self-discrepancy theories are important in guiding therapeutic interventions as well as the importance of further research on the implicit measurements of self-esteem. The IRAP is an assessment measure that was piloted in two studies and was found to be in line with the previous research regarding the effectiveness of the IAT and that the IRAP is as equally effective as the IAT.

Rational Emotive Behavioral Therapy (REBT) is concerned with treating irrational beliefs by replacing them with rational beliefs. Research on implicit and automatic processes has shown that behavior is in part controlled by automatically triggered impulses and stimuli which are connected to a reflective system. Explicit low self-esteem has been correlated with several psychological disorders such as depression and eating disorders. REBT theories differentiate between self-esteem and unconditional self-acceptance. Group Cognitive-Behavioral Therapy (GCBT) was also found to be a helpful intervention to improving and/or maintaining one's self-esteem. Several studies have examined the effectiveness of both cognitive assessments and self-report assessments. The Cognitive Distortions Scale (CDS) when used in conjunction with the

RSES was found to be a significant indicator of cognitive distortions and their relationship with self-esteem.

Limitations for measuring self-esteem come not only in their uses on a global or cross-cultural scale, but also from counselors and other qualified mental health professionals incorrectly using these assessments. In other words, these professionals are not using the assessments to ascertain the self-esteem level or do not use the results of these assessments as a serious part of the treatment for the patient. Some of the controversial limitations with self-esteem both in general and in the assessing of self-esteem levels involve the defining and terms used for self-esteem.

Self-monitoring (to include the Self-Monitoring Scale), Assessment of

Justin M. Shepherd[1] and Karen Meteyer[2]

[1]*University of Houston*
[2]*Antioch University New England*

Self-monitoring

Self-monitoring is a personality dimension that refers to the extent to which individuals modify their verbal and non-verbal self-presentation and expressive behavior in social situations. The goals of self-monitoring individuals are to: (1) accurately communicate authentic emotional states when appropriate; (2) communicate arbitrary emotional experiences when expected; (3) conceal improper emotional states; and (4) create the impression of experiencing an emotion when feeling none (Snyder, 1974). Accordingly, Self-Monitoring Theory is constructed on the premise that people differ meaningfully in the degree to which they choose to display their private selves in public situations (e.g. high self-monitors vs. low self-monitors). Individual differences in self-monitoring may help explain the discrepancy between private identities and public appearances.

High vs. Low Self-monitors

High self-monitors are attuned to the social cues of other individuals in social contexts (Snyder, 1979). Sensitivity to external indications of situational appropriateness tends to guide high self-monitors' self-presentation and expressive behavior. Acutely aware of social cues, high self-monitors adjust the public presentation of their expressive behavior to fit the situational context (e.g. acting sad when others are sad). The expressive self-presentation of high self-monitors in social contexts is dependent upon the situational appropriateness in an attempt to create an idealized public appearance (Snyder, 1979).

By contrast, internal cues (e.g. affective states, inner attitudes, and dispositions) are the driving forces that direct the expressive behavior and self-presentation of low self-monitors (Snyder, 1979). Accordingly, low self-monitors' apathy for situational appropriateness and disregard for expressive control guide their behavior in social situations. Unlike high

self-monitors, social cues are of little influence to low self-monitors who tend to overtly express their true inner feelings (Snyder, 1979). Low self-monitors exhibit a consistent cross-situational expression of behavior; there is congruence between the expressive self-presentation of low self-monitors and their private identities.

For decades psychologists have debated the relative influence of situational versus trait-based explanations of individuals' attitudes and behaviors. The theoretical construct of self-monitoring provides a potential resolution to the clash of schools of thought. For high self-monitors, behavior is interpreted as the product of situational factors whereas for low self-monitors, traits or dispositions predict behavior (Gangestad & Snyder, 2000). Attitudes explain the actions of low self-monitors but are not the best predictors of behavior for high self-monitors (Gangestad & Snyder, 2000). An acceptable solution to the principal opposition between both disciplines is that low self-monitors fit the trait-oriented concept of personality psychology while high self-monitors exemplify the situation-orientation view of social psychology.

The Self-Monitoring Scale

The Self-Monitoring (SM) Scale is a frequently administered personality measure for research purposes. The original 25-item SM Scale was developed to assess individual differences in self-monitoring tendencies (Snyder, 1974). The items measured five dimensions of self-monitoring: (1) concern with social appropriateness; (2) attentiveness to social cues for apt self-presentation; (3) regulation of expressive self-presentation; (4) situational specificity of expressive behavior and self-presentation control; and (5) adaptability of expressive behavior and self-presentation in different contexts (Snyder, 1974). While the 25-item SM Scale was developed to assess the five dimensions of self-monitoring, factor analysis demonstrated that the SM Scale did not measure distinct components but rather yielded a three-factor solution: Acting, Extraversion, and Other Directedness (Gangestad & Snyder, 2000). As a result, a primary controversy regarding the measurement of self-monitoring concerns whether or not self-monitoring is best explained by multiple factors as opposed to the unitary conceptualization (Fuglestad & Snyder, 2009).

A shorter revised SM Scale, which retains 18 of the 25 original items, was developed to address the multidimensionality found within the original 25-item measure. With a higher internal consistency, the general consensus is that the revised SM measure is more psychometrically sound (Gangestad & Snyder, 2000). Examples include: "I find it hard to imitate the behavior of other people" and "I guess I put on a show to impress or entertain others." Participants typically respond to the SM Scale in a "true" or "false" format. Items on the SM Scale are scored in the direction of high self-monitors. Despite disagreement regarding the optimal assessment and conceptualization of self-monitoring, the lasting popularity of the SM Scale seems to suggest that it assesses a noteworthy construct.

Both the 25- and 18-item SM Scales demonstrate internal consistency and test-retest reliability (Snyder & Gangestad, 1986). The scale is also robust to the effects of social desirability and other issues of response styles. Both the 25-item and 18-item SM Scales appear to be valid measures of self-monitoring as research comparing self-monitoring with similar constructs (i.e. need for approval, Machiavellianism, and extraversion) has demonstrated the

discriminant validity of the SM Scale (Snyder, 1979). The list of constructs with which self-monitoring is *not* meaningfully related is extensive, suggesting that self-monitoring is a distinctly unique construct (Snyder, 1979).

Revised Self-Monitoring Scale

The Revised Self-Monitoring Scale is a 13-item measure developed in response to criticism of the original 25-item SM Scale in order to provide a focused re-conceptualization of self-monitoring that measured responsiveness to the expressive behavior of others and aptitude for self-presentation modification (Lennox & Wolfe, 1984). Participants are asked to specify the degree to which each item mirrors their own behavior on a 6-point Likert-type scale: 0 = *certainly, always false* to 5 = *certainly, always true*. Examples include: "In social situations, I have the ability to alter my behavior if I feel that something else is called for" and "I am often able to read people's true emotions correctly through their eyes." Higher scores are representative of increased self-monitoring tendencies. The Revised SM Scale yields two subscales: ability to modify self-presentation (seven items) and sensitivity to the behavior of others (six items; Lennox & Wolfe, 1984). Scores can be summed within the two factors and interpreted according to the factor indices or as an overall measure of self-monitoring.

Junior Self-Monitoring Scale

The Junior Self-Monitoring Scale (JSMS) was designed to measure differences in self-monitoring tendencies among children (Graziano, Leone, Musser, & Lautenschlager, 1987). The JSMS consists of 24 items, 12 of which correspond to the adult SM Scale. Examples include: "I like to know how my classmates expect me to act and I can make people think I'm happy even if I'm not happy." Participants respond to the JSMS in a "yes" and "no" format and the measure is scored in the direction of high self-monitoring. The JSMS was constructed to mirror the five dimensions of self-monitoring represented in the original SM Scale but is more age-appropriate for the experiences of children (Graziano, Leone, Musser, & Lautenschalager, 1987).

Application to Other Life Domains

Self-monitoring has evolved from its contextual focus on the monitoring of public appearances and self-presentation to encompass a variety of other important life domains including interpersonal relationships as well as consumer and organizational behavior. Evidence has emerged to suggest that the primary distinction between low and high self-monitors is a focus on the internal world (e.g. attitudes and dispositions) for low self-monitors and the influence of the external world (e.g. appearances and roles) on high self-monitors.

Interpersonal Relationships

Just as high and low self-monitors differ in the extent to which they exercise control over expressive behaviors, so too do they differ in their conceptualization of friendships and romantic relationships. High self-monitors tend to select their friends based on shared interests (Fuglestad & Snyder, 2009). That is, the social worlds of high self-monitors are segregated such that certain people are favored over others for particular activities. While interactions with friends of high self-monitoring individuals are often classified as short and rather artificial, low self-monitors choose to engage in long and meaningful conversations. Friendships of low self-monitors are more likely to be formed on the basis of shared values rather than common activities (Fuglestad & Snyder, 2009).

The typical romantic relationship pattern of low self-monitors is characterized by a desire for an intimate, long-term relationship (Fuglestad & Snyder, 2009). Low self-monitors choose partners on the basis of compatibility and emphasize similar values. Honesty, loyalty, and kindness are the primary characteristics low self-monitors admire when selecting a partner. High self-monitors are most interested in attractiveness, sex appeal, and social status when selecting a partner. For high self-monitors who view love as a social game and have a non-committal attitude toward intimate relationships, philandering is not an uncommon occurrence (Fuglestad & Snyder, 2009).

Consumer Attitudes and Behavior

Self-monitoring orientations also affect receptiveness to advertising and consumer decision-making. Advertising strategies typically emphasize either image-oriented campaigns (e.g. "soft" sell) or focus on the practicality and quality of a product (e.g. the "hard" sell; Fuglestad & Snyder, 2009). Concerned with self-presentation and social appropriateness, image-oriented advertisements appeal more favorably to high self-monitors. In contrast, low self-monitors who value congruence between how they feel and behave are more responsive to quality-oriented advertising. Accordingly, the same pattern holds for advertising strategies designed to prevent consumers from engaging in a particular behavior (e.g. smoking).

Beyond advertising, the influence of self-monitoring is also apparent in consumer decision-making. The consumer decisions of high self-monitors are frequently made on the basis of external appearance and are influenced by the attractiveness of a product. By contrast, the consumer behavior of the prototypical low self-monitor is based on the internal characteristics of the product (Fuglestad & Snyder, 2009).

Organizational Behavior

In expanding the self-monitoring line of inquiry to encompass organizational behavior, high self-monitors focus on outward appearance in social situations, relationships, and advertising, which also extends to employment decision-making. Low self-monitors are more likely to hire an employee based on the candidate's personality fit for the job whereas

high self-monitors tend to hire applicants based on external appearance (Fuglestad & Snyder, 2009). When deciding which jobs to pursue, low self-monitors tend to select positions that mesh well with their own personalities while the prototypical high self-monitors prefer clearly defined positions that allow them to adjust their behavior to fit the role (Fuglestad & Snyder, 2009).

Self-regulation, Assessment of

Lauren M. Littlefield

Washington College

Self-regulation entails purposeful management of oneself. McClelland and Cameron (2012) provide a clear, general definition of self-regulation: "controlling or directing one's attention, thoughts, emotions, and actions." It is generally agreed upon that the core feature of self-regulation involves asserting internal control. In essence, this means monitoring and adjusting performance in accordance with current demands. Response patterns are dictated by potential rewards being contrasted with existing threats and punishments. Self-regulated individuals can effectively adjust their behavior in accordance with situational expectations.

Many words have been substituted for the term self-regulation: executive functioning; executive control; self-control; inhibition; self-management; and self-monitoring. Related terms are often used interchangeably, leading to potential confusion. Adopting the American Psychological Association's controlled vocabulary, Burman, Green, and Shanker (2015) conducted a modularity analysis and mapped the semantic network for self-regulation to reveal six main clusters: (1) self-monitoring/self-management/self-evaluation; (2) self-monitoring/personality traits/reflectiveness; (3) agency/locus of control/self-determination; (4) self-control; (5) social behavior; and (6) learning/learning strategies. Terms across clusters are conceptually similar but may have nuanced, and perhaps essential, differences.

Measuring Self-regulation across the Fields of Psychology

Dinsmore, Alexander, and Loughlin (2008) studied the historical trajectory of self-regulation research, which evolved into several related lines. Originally, emotional and behavioral self-regulation were emphasized. The study of motivation grew from this line of work. The metacognitive perspective came about in parallel, emphasizing self-awareness of thinking. A focus on self-regulated learning came about later and was specific to an academically based environment. Expansions of research in other settings evidenced how self-regulation

capabilities impact health, sports, and career arenas. Modern conceptualizations often discuss self-regulation as a cognitive concept. The subsections that follow address how different fields within psychology conceptualize and measure self-regulation.

Clinical and Developmental Psychology

The clinical literature addresses failures of self-regulation. It is known that self-regulation is weakened by diagnosed psychopathology. Since impulsive behavior is rarely adaptive and can be destructive, poor self-control is central to a number of diagnosed disorders. When driven by unleashed emotions, a variety of problem behaviors can develop, such as delinquency, gambling, drug/alcohol overuse, suicide attempts, hyperactivity, aggression, and binge eating. Even unwanted habits like nail biting or nose picking are examples of the inability to control behaviors that are maladaptive and perhaps self-injurious. Some practitioners would say that Attention-Deficit/Hyperactivity Disorder with prominent hyperactive and impulsive features is the quintessential example of poor self-regulation. The person knows right from wrong but may not think before acting.

Clinical psychologists typically use interviews, observations, and rating scales to measure poor self-control or impulsivity. The Barratt Impulsiveness Scale and the UPPS Impulsive Behavior Scale are commonly employed self-report rating measures. Impulsiveness appears to be multifaceted, and can include factors such as a sense of urgency, racing thoughts, the tendency to act quickly, and a lack of planning. Behavioral manifestations of impulsivity can be witnessed, but rating scales help to pinpoint underlying personality and cognitive factors.

Gaining control over emotions and behavior is of interest to developmental psychologists. Research simulations incorporating practical scenarios are used to investigate impulsivity. For instance, tempting, demanding, or upsetting situations can be used to better understand temperamental reactivity. Extreme emotions or an instant gratification mindset can change one's sense of priorities. Mischel's classic marshmallow test examines impulse control. In this laboratory method, a small immediate reward is offered (such as a tasty marshmallow), with the provision that a larger reward will be supplied (two marshmallows) if the child waits for a period of time before consuming the initial reward. Children who can delay gratification tend to have better real-world outcomes, such as higher cognitive scores and stronger academic performance.

Educational Psychology

To become productive members of society, children must develop enough self-control to be capable of learning. Emotional control and positive social skills in young children appear to be more predictive of preschool- and school-readiness than intelligence or achievement scores. Moreover, poor self-regulation has been associated with peer rejection and negative attention from teachers. Self-regulation allows for an intentional, motivated approach to learning wherein students sustain attention to lessons and assignments yet inhibit activities that would interfere with their educational goals. Self-regulated learners can set goals, enact cognitive strategies, monitor their progress, and reflect upon their learning experiences.

Structured interviews and questionnaires are often used to assess use of learning strategies and motivating factors versus amotivating factors (like anxiety). Some research in self-regulated learning has used teacher ratings of pupil behavior. Students can be asked to perform an academic task and rate their perceived ability at that type of task. Rating scales standardly inquire about metacognitive strategies like planning and reflection on the learning process. Personal evaluations of self-efficacy and level of effort are also commonly considered.

Social and Personality Psychology

Human learning and behavior occur through social interactions. People tend to choose relationships with those who have similar goals. While people vary in attitudes, values, and level of motivation toward certain tasks, they are generally more accepted by others when they conform to the prescribed set of expectations valued in that environment. Through appraising the social and emotional importance of a given action, people can predict if their behavior may be accepted or be considered deviant. These decisions are sometimes conceptualized as the conflict between approaching and avoiding a certain situation.

Personality and social psychologists often discuss self-regulation by its relationship with the Big Five traits. When it comes to approach-avoidance conflicts, Extraversion and positive affect are associated with approaching situations while Neuroticism and negative affect are related to withdrawal tendencies. A cautious, thoughtful approach seems to generally result in positive management of behavior, especially in novel situations. Therefore, higher Conscientiousness has been related to self-control. Isler, Liu, Sibley, and Fletcher (2016) found that those who are too reward-focused yield higher scores on Openness and Extraversion. They also identified a "brittle profile," or the personality style seen in those who are not resilient and thus tend to experience poor interpersonal outcomes. Brittle people have higher Neuroticism scores combined with lower scores on all other Big Five traits (i.e. Extraversion, Openness, Agreeableness, Conscientiousness).

Other personality tools facilitate the measurement of self-regulatory prowess. Self-appraisal inventories assess personal evaluation of general self-esteem or self-efficacy in focused areas. Locus of control questionnaires can be useful because high self-regulation has been related to having an internal locus of control. Those with an internal locus of control believe they can have a direct impact on their personal circumstances as opposed to feeling like luck and fate are involved. Emotional intelligence (EI) encompasses management of emotions as well as self-awareness and empathy for others. Various EI measures contain scales of self-management, impulse control, self-control, and self -regulation.

Cognitive Neuropsychology and Neuroscience
Functional imaging evidence has fairly conclusively determined that conscious, goal-directed behavior (or executive functioning) is facilitated by the prefrontal cortices of the brain. A break-down in self-regulation exists in cases of injury to the frontal lobes. Damage typically results in dysregulation of thoughts, behaviors, and emotions.

Control over thinking can be unobtrusively measured. Flexible thinking, inhibitory control, and working memory are three main aspects of executive functioning that can be assessed through standardized neuropsychological measures. Well-known measures include the Wisconsin Card Sorting Test, the Stroop, stop-signal tasks, continuous performance tests, and span tasks. The Wisconsin requires the test-taker to flexibly sort cards based on changing examiner feedback. This involves deftly shifting between different concepts. The Stroop, a measure of inhibition, is a timed task. Subjects are expected to say the color of the ink that words are printed in as opposed to reading the words themselves. For instance, when the word blue is printed in green ink, the examinee needs to suppress the natural response to read blue and instead say green. Inhibition can also be assessed through stop-signal (or go/no-go) tasks wherein subjects are asked to respond one way when faced with a certain signal but to stop responding when a different signal is present. Continuous performance tests assess monitoring and inhibition; monotonous visual or auditory stimuli are presented, with the task being to only respond when a specific type of stimulus occurs. Traditional working memory measures require an examinee to temporarily hold and process information. There are many types of span tasks, but one example involves computing math problems while simultaneously recalling words that appear on a computer screen after each math operation.

The field of neuroscience brings dynamic brain imaging evidence that reveals top-down processing is controlled in the prefrontal cortex (where decisions are made about both social and cognitive matters) while bottom-up processing from the emotional limbic lobe is being processed simultaneously. Using this dynamic brain processing model, literature on *hot* processing (i.e. dealing with emotional reactivity) and *cool* processing (i.e. predominantly cognitive in nature) can be integrated. Hofmann, Schmeichel, and Baddeley (2012) connect the *hot* and *cool* lines of research by pointing out that cognitive processes allow for social and emotional control. For example, enhancing working memory capabilities can generalize to reduce problem eating and alcohol-using behaviors.

Conceptual Conclusions and Future Directions

Across fields of psychology, operational definitions of self-regulation and its related terms can be clarified. Dinsmore and colleagues (2008) uncovered an "undeniable conceptual core" between the terms self-regulation, metacognition, and self-regulated learning, but warned that the "conceptual haze" will only become fuzzier if distinctions are not made. Schunk (2008) recommends clearer, standardized, theoretically based definitions and assessment of cognitive control processes like metacognition, self-regulation, and self-regulated learning in order to better arrive at distinctiveness between concepts. When well-delineated definitions are applied, precise measurement tools can be chosen or developed to better align with conceptual understanding.

To fully encapsulate the complexities of human behavior, Collins and colleagues assert that complete theories of personality need to incorporate an inhibitory process (Collins, Jackson, Walker, O'Connor, & Gardiner, 2017). Inhibition, or the ability to restrain one's behavior, has been studied across a range of personality variables and cognitive variables.

While much work has attempted to articulate the distinction between cognitive process and personal tendencies (i.e. the underlying personality), it appears both personal inclinations and mental processes contribute to a person's self-regulation capabilities. Most specifically, a convergence of evidence points to the idea that mental mechanisms are needed to explain personality differences.

With a growing focus on measuring cognitive variables, self-report measures still appear to be the most common method to assess components of self-regulation. However, the study of stable personality traits may not tell the whole story. Experimental simulations can assist in appreciating how the changing environmental context impacts personality and emotional states. Participants can be placed in specific situations so that information can be collected through observation, interview, think-aloud protocols, or journaling/diaries. Most importantly, to fully understand the complex processes involved in self-regulation, qualitative measures need to be combined with performance-based, cognitive scores. Approaching the same concept from different angles or theoretical orientations should further conceptual understanding. For instance, an interdisciplinary method could assess impulsivity as a personality variable while comparing it to measures of cognitive inhibition.

[2]*Rivier University*

Self-consciousness

Self-consciousness (SC) involves the process of becoming the object of one's own attention and awareness. Based on theories stemming back decades, self-consciousness has been conceptualized and subsequently operationalized in many different ways over the years. The most well-known and widely used measure of self-consciousness was developed by Feningstein, Sheier, and Buss (1975) and includes the three domains of private self-consciousness, public self-consciousness, and social anxiety. Self-consciousness has been found to relate to a number of other constructs including sensitivity to peer rejection, level of aggression following a threat, acceptance of responsibility, self-esteem, anxiety and depression.

Recent frameworks describe self-consciousness as a form of self-reflection which can be associated with either psychological well-being (i.e. adaptive self-consciousness) or psychological distress and negative affect (i.e. maladaptive self-consciousness) and have explored the connection of self-consciousness to related constructs such mindfulness, self-absorption, and self-rumination. Maladaptive, or unhealthy, self-consciousness occurs when self-attention is excessive and narrow, and has been found to be related to several negative mental health outcomes. If there are inconsistencies between the self and expectations, the subject may readjust how they view themselves and/or their personal standards in order to promote consistency and a positive image. This occurs in both public and private self-consciousness, depending on the direction of focus (DaSilveira, DeSouza, & Gomes, 2015).

The Self-Consciousness Scale

The original Self-Consciousness Scale (SCS), developed by Feningstein, Sheier, and Buss (1975) is a 23-item scale designed to measure an individual's tendency to focus attention on the self. The scale reflects three dimensions of self-consciousness private

self-consciousness, public self-consciousness, and social anxiety within the individual. Public self-consciousness consists of a general understanding that the self has a social effect on others (e.g. "I'm concerned about what other people think of me"; "I usually worry about making a good impression") while private self-consciousness focuses on attending to inner thoughts and feelings (e.g. "I'm always trying to figure myself out"; "I'm often the subject of my own fantasies").

Social anxiety is viewed as distress which occurs in the presence of others. Both public and private self-consciousness include self-focused attention whereas social anxiety occurs in reaction to these feelings (e.g. "It takes me time to overcome my shyness in new situations;" "I feel anxious when I speak in front of a group"). When attention is turned inward, a person might develop anxious thoughts and as such, anxiety might emerge due to either public or private self-consciousness (Fenigstein, Scheier, & Buss, 1975). Though correlated, the authors argue that public self-consciousness is distinct from social anxiety in that not all individuals who are conscious of themselves as social objects necessarily develop anxiety regarding that perception.

Though used extensively in the literature, the Self-Consciousness Scale is not without controversy. Questions regarding the theoretical foundation as well as the number of factors have been raised. Some have proposed that the dimension of public self-consciousness be further divided into "style consciousness" (awareness of behavior observed by others) and "appearance consciousness" (focus on how one looks to others) or alternatively into "self-reflectiveness" (emphasizing self-exploration and self-evaluation) versus "internal state awareness" (i.e. focus on feelings and physiological reactions).

The Revised Self-Consciousness Scale

Tested extensively with undergraduate students, the original 23-item Self-Consciousness Scale (Fenigstein, Sheier, & Buss, 1975) was later revised by Scheier & Carver (1985) to improve comprehensibility in the general population. The Revised Self-Consciousness Scale consists of 22 items based on the original scale but modified to be less abstract (e.g. "I'm often the subject of my own fantasies" to "I often daydream about myself"; "I feel anxious when I speak in front of a group" to "I feel nervous when I speak in front of a group"). The current scale also modified the response format from the original scale (i.e. 0 = extremely uncharacteristic, 4 = extremely characteristic) to more precise rating answers (i.e. 3 = a lot like me, 2 = somewhat like me, 1 = a little like me, 0 = not at all like me). In order to assess the reliability of the revised scale, 298 undergraduate students completed both the original and revised scale. Results suggested that participants performed similarly on both versions of the scale, though researchers recommend the revised version be used with general (non-college student) populations.

Though the question of the number of factors and sub-factors has continued to be tested and retested with different populations, the original 3-factor solution proposed by Fenigstein, Sheier, and Buss (1975) consisting of private self-consciousness, public self-consciousness and social anxiety has largely been upheld. The Self-Consciousness Scale has been used in hundreds of published studies and has been translated into numerous languages and tested in multiple countries in Europe, North America, South America, Asia and the Middle East.

The Self-Consciousness Scales for Children

The Self-Consciousness Scales for Children (SCS-C; Abrams, 1988) includes 15 items based on the adult version. Higa, Philips, Chorpita, and Daleiden (2008) subsequently created a 28-item scale for use with children as well. The Higa et al. (2008) measure was further modified in 2014 by Takisihima-Lacasa, Higa-McMillan, Ebesutani, Smith, and Chorpita resulting in the Revised Self-Consciousness Scale for Children (R-SCS-C). Research on the Revised Self-Consciousness Scale for Children suggests that a similar 3-factor solution based on private self-consciousness, public self-consciousness and social anxiety can be found across age and gender.

Additional Features of Self-consciousness

In addition to the feature of private/public, researchers have also explored the dimensions of past/present and adaptive/maladaptive self-consciousness. According to DaSilveira, DeSouza, and Gomes (2015), the past/present features of self-consciousness are divided by two approaches: the reflective approach and the present approach. The reflective approach is connected to private self-consciousness and states that the perception one has about their current self is influenced by the perception of their past or future selves. More specifically, this perspective requires the individual to reflect on a previous experience, evaluating thoughts, feelings, and behaviors.

Conversely, the present approach assumes that self-consciousness can be associated with the present moment without reflecting on the past or future. This school of thought focuses on mindfulness, which involves maintaining consistent attention to the present and expressing an open attitude toward current experiences (DaSilveira, DeSouza, & Gomes, 2015). Regardless of the individual's approach, regulating one's internal processes can lead to either adaptive or maladaptive self-conscious reactions or responses.

The adaptive/maladaptive features of self-consciousness encompass the paradox of focusing on one's self. Although helpful for reflection, awareness, and well-being, self-attention can also lead to negative emotions. As a result, it is important to recognize the distinction between the benefits of becoming aware of one's beliefs as well as the detriments of excessive self-focus. Maladaptive self-attention occurs as a self-regulation process when self-evaluation and standards are inconsistent. This contradiction often leads to negative psychopathological states, such as depression and anxiety. As such, it is not surprising that most psychological disorders are characterized by amplified self-focused attention, in which the individual creates impossible, unattainable standards. Though this can be seen as maladaptive, with proper treatment, these experiences, behaviors, and thoughts can act as an opportunity for self- evaluation. For instance, an individual with a psychological disorder may experience inconsistencies with public and/or private self-consciousness and adjust their behavior through therapy and self-regulation of symptoms (DaSilveira, DeSouza, & Gomes, 2015).

Future Directions

With the increase in social networking activity, displays of public and private information about the self may be changing. Recent research using the Self-Consciousness Scale has explored how the construct relates to the increasing popularity of social media.

Shim, Lee, and Park (2008) found that public self-consciousness was positively associated with a greater frequency of posting photos and replying to comments. Posting photos online is rewarding to those with high public self-consciousness because it allows them to manipulate their outside impression more successfully. Users may spend unlimited time posing and editing photos before posting them online. This process enhances the impression one may have on other users, increasing the perception of positive public self-consciousness.

Current research has not yet assessed how online public self-consciousness may be distinct from earlier definitions of self-consciousness and how this relates to private self-consciousness and social anxiety among social media users. Content on such applications presents individuals with an immediate presence of peers and perceived social standards. Users may be presented with reminders of unrealistic standards, such as those associated with body image. Future research should consider exploring how different aspects of self-consciousness relate to social networking behaviors.

Subjective Well-being, Assessment of

Kimberly B. Dasch-Yee

Holy Family University

The study of subjective well-being aims to go beyond just the absence of illness, anxiety (see Anxiety for a discussion of the conceptualization of anxiety and Anxiety, Assessment of for a discussion of the assessment of anxiety), depression (see Depression for a discussion of depression), or other psychological symptoms. Rather than being just the absence of the negative, subjective well-being is a positive state of satisfaction or contentment. However, there are many diverse ways that subjective well-being is conceptualized and measured. For example, the exact operational definition, that is, way the construct is measured or defined, varies greatly between measures of subjective well-being. Some measures use the term well-being, while others use the terms satisfaction with life, quality of life, happiness, or flourishing. In addition, some researchers measure subjective well-being on a one-dimensional scale, so that there is only one well-being, satisfaction with life, or quality of life score generated by the measure. However, other measures have been created that provide a multi-dimensional depiction of a respondent's well-being, with several subscales for the measure. Depending on the researchers' or clinicians' goals, the most appropriate measure of subjective well-being may vary. Several commonly used measures of subjective well-being are described below, with a description and a discussion of some of the unique features and advantages of each measure.

Satisfaction with Life Scale

The Satisfaction with Life Scale (SWLS; Diener, Emmons, Larsen, & Griffin, 1985) measures global life satisfaction. The measure was designed to focus on life satisfaction only, and by design does not measure positive and negative affect (see Positive and Negative Affective States, Assessment of for a discussion on assessing positive and negative affect) or other constructs, such as loneliness (see Loneliness for a discussion of assessing loneliness). The SWLS conceptualizes satisfaction with life as a cognitive-judgmental process, meaning that an individual's satisfaction with life is a result of a comparison of one's life circumstances

to what the person believes to be an appropriate and relevant standard. This standard is internally set by each individual; it is not externally determined by others. Each person may judge different domains, such as health or energy, to be of more or less importance. Therefore, the SWLS measures life satisfaction as a global construct, rather than as the result of a summary of satisfaction scores across individual domains. There are five items, each answered on a seven-point Likert-type scale with 1 = *strongly disagree* and 7 = *strongly agree*. Final scores range from 5, indicating low life satisfaction, to 35, indicating high life satisfaction. Examples of items on the SWLS include: "In most ways my life is close to ideal," "The conditions of my life are excellent," and "I am satisfied with my life." The SWLS was developed using both college student and older adult populations and is appropriate to use with different age groups. Internal consistency and test-retest reliability were both found to be high.

The Psychological Well-being Scales

The Psychological Well-being Scales (Ryff, 1989) sought to operationalize several theoretical domains that were believed to be related to psychological well-being. The scales specifically measure well-being along six separate domains of psychological well-being. Those domains include *self-acceptance*, that is having a positive view toward oneself; *positive relations with others*, that is having warm, trusting relationships with others; *autonomy*, that is being independent and self-determined; *environmental mastery*, that is having the ability to manage the environment; *purpose in life*, that is having life goals and a sense of directedness; and *personal growth*, that is experiencing the feeling of continued growth. The original scales had 20 items per scale, although shorter versions have since been developed. Each item is responded to on a 6-point scale indicating level of agreement with each item, ranging from *completely disagree* to *completely agree*. The measure was developed using a mixed-age population that included younger, middle-aged, and older adults. Confirmatory factor analysis supported the six-subscale structure. Internal consistency and test-retest reliability were both found to be high.

Quality of Life Inventory

The Quality of Life Inventory (QOLI; Frisch, Cornell, Villaneuva, & Retzlaff, 1992) is a clinically oriented measure of quality of life that is domain-based, rather than global in its assessment. The QOLI has 17 items, each of which are rated on importance to the respondents' happiness and satisfaction on a 3-point scale (0 = *not at all important*, 1 = *important*, and 2 = *extremely important*). Each item is also rated on the respondents' satisfaction in that domain on a scale from −3 = *very dissatisfied* to 3 = *very satisfied*. For each item, a weighted score is then calculated, taking into account both the importance and satisfaction in each area, by multiplying the importance rating by the satisfaction rating. The resulting weighted score for each item ranges from −6 to 6. The overall QOLI score is then calculated by averaging the weighted scores for all items that have non-zero importance ratings.

The QOLI measures importance and satisfaction on 17 domains, health, self-regard, philosophy of life, standard of living, work, recreation, learning, creativity, social service, civic action, love relationship, friendships, relationships with children, relationships with relatives, home, neighborhood, and community. The QOLI was developed using a number of samples, including inpatient VA patients seeking treatment for alcohol dependence or abuse, former VA patients who had previously sought treatment for alcohol dependence or abuse, patients seeking alcohol and drug abuse treatment at a private hospital, students at a college counseling center, undergraduate psychology college students, and individuals who were criminal offenders on probation in a structured rehabilitation program. A particular strength of the QOLI is that because it was designed to be used in clinical settings, it may be especially appropriate to measure treatment progress, assess the effectiveness of interventions, and to assist in treatment planning. The QOLI was found to have strong internal consistency and test-retest reliability.

Oxford Happiness Questionnaire

The Oxford Happiness Questionnaire (OHQ; Hills & Argyle, 2002) measures personal happiness on a one-dimensional scale. It is derived from the Oxford Happiness Inventory (OHI), which has four response options that are different for each item. The OHQ, however, uses a less bulky uniform response scale. Specifically, the OHQ consists of 29 items, all of which are responded to on a 6-point Likert-type scale (1 = *strongly disagree* to 6 = *strongly agree*). About half of the items are reverse scored, which should be helpful in determining whether participants are carefully reading and responding to the questions. In addition, since the respondents answer on a uniform scale, the items can be more easily mixed together with items from other scales to reduce bias when answering the questions. A shorter version of the OHQ, which consists of eight items, was also developed to use when time is more limited. Examples of items on both the longer and shorter versions of the OHQ include: "I feel that life is very rewarding," "I am well satisfied with everything in my life," "I find beauty in some things," "I do not have particularly happy memories of the past," and "I don't feel particularly pleased with the way I am," with the last two items being reverse coded. The OHQ was developed using an undergraduate student sample, as well as the students' friends and family members. The OHQ was found to have adequate internal consistency reliability and construct validity.

Subjective Happiness Scale

The Subjective Happiness Scale (Lyubomirsky & Lepper, 1999) is a global measure of subjective happiness, meaning an overall rating of whether an individual considers him or herself to be a happy or unhappy person. The scale consists of four items. Specifically, one item asks respondents to rate how happy they consider themselves, with another item asking them to rate how happy they consider themselves as compared to their peers. Two other items provide descriptions of happy and unhappy people and ask the respondents to

indicate the extent to which the portrayal describes them. Each of the items is rated on a 7-point scale. For the ratings of happiness for themselves and their peers, 1 indicates less happiness and 7 indicates more happiness. For the descriptions of happy and unhappy people, 1 indicates the characterization does not at all describe them and 7 indicates the characterization greatly characterizes them. A composite score is then calculated by averaging the responses to the four items, with one item (the item with a description of unhappy people) being reverse coded. The Subjective Happiness Scale was developed with college and high school students, as well as working and retired adults, with participants from both the United States and Russia, making for a sample with diverse ages and backgrounds. One particular advantage of the measure is that it is relatively short, so as to not overburden the participants. The Subjective Happiness Scale was found to have strong internal consistency, test-retest reliability, convergent validity, and discriminant validity.

Flourishing Scale

The Flourishing Scale (Diener et al., 2010) measures the degree to which the respondent perceives personal success in important domains of functioning, such as relationships, competence, and having purpose in life. The scale was originally called Psychological Well-being, but the name was changed to reflect that the content of the scale is broader than just psychological well-being. The measure has 8 items, which are all rated on a scale from 1 (*strong disagree*) to 7 (*strongly agree*). The scale results in one global score, reflecting the respondents' perceptions of themselves across diverse domains of human functioning, such as relationships, self-esteem, purpose, and optimism. All items are scored in a positive direction, with resulting scale scores ranging from 8 (*strong disagreement with all items*) to 56 (*strong agreement with all items*). A high score indicates respondents have a positive view of themselves in these important areas of functioning. Examples of items on the scale include "I lead a purposeful and meaningful life," "My social relationships are supportive and rewarding," "I am engaged and interested in my daily activities," "I am competent and capable in the activities that are important to me," and "I am optimistic about my future." The measure was developed using a college student sample from across the United States as well as Singapore. The Flourishing Scale demonstrated strong internal consistency, test-retest reliability, and convergent validity.

California Psychological Inventory (CPI)

Cory L. Cobb[1], Dong Xie[1], and Alexandros Maragakis[2]

[1]*University of Central Arkansas*
[2]*Eastern Michigan University*

Originally developed by Harrison Gough (1956), the California Psychological Inventory (CPI) is a self-report personality measure composed of 434 true-false items. The test contains information regarding a person's typical behavioral patterns, feelings and opinions, and attitudes centered on social, familial, and ethnic concerns. Although the CPI was primarily developed for young adults in the general population, the test has been used to evaluate individuals with ages ranging from 12 to 70. Results of the CPI are plotted on 20 scales and three factors that examine components of interpersonal relationships that are presented in everyday, descriptive language.

The philosophical underpinnings of the CPI are based on common and enduring personality factors that are thought to be relevant across cultures including dominance, self-control, and tolerance. Gough referred to these common variables as "folk concepts" because they are common and easily understood. According to Gough, the use of such concepts provides the CPI with cross-cultural relevance, ease of comprehension, and strong predictive power. As such, the focus of the CPI centers on practical utility, understandability, and predictive accuracy. For these reasons, the CPI is one of the most frequently used personality measures used by professional psychologists, with more than 2,000 studies having used or researched it.

Although the CPI was designed to be easily understood, competent interpretation requires a trained professional. Within the structure of the test are sophisticated factors that need to be cautiously considered and explained. Interpretation of the CPI involves taking into consideration scores within an individual's overall context (e.g. age, culture, and history), evaluating the interactions between two or more scales, and identifying person-specific trends pertinent to each test-taker. For example, a recent high school graduate's high score on the Intellectual Efficiency scale may be low for a person who recently graduated from a graduate program.

History and Development of the CPI

The CPI was initially developed to evaluate relatively enduring interpersonal and personality traits in the normal population. Gough published his original scales in 1948, but it was not until 1951 that the first copyrighted version of the 15 scales appeared. In 1957, a completed set of 18 scales was published by Consulting Psychologists Press (CPI 480). The CPI was further revised in 1987 (CPI 462) with two scales being added (Empathy and Independence), resulting in a total of 20 scales. The resulting 20 scales measure areas of personality such as social image, intellectual stance, and interests. Also, three of the scales are validity scales which measure test-taking attitudes (i.e. fake good and fake bad) and the extent to which popular responses are recorded. In an effort to comply with the 1990 Americans with Disabilities Act, the CPI underwent another revision in 1996 (CPI 434). While this revision resulted in 28 items being deleted (now a total of 434 items), the 1987 scales and vectors were retained. Finally, a short form of the CPI was developed in 2002 (CPI 260).

The CPI was developed without a particular personality theory or theory of pathology in mind. Rather, the 1957 version of the CPI was developed using both an empirical and rational approach. Specifically, the items on the CPI were derived from a pool of 3,500 questions, each of which was posited to conceptually measure the construct the scales were intended to measure. The measure resulted in 468 items, 178 of which were identical to MMPI items, 35 were similar, and 255 were exclusive to the CPI. The questions were given to a sample group and subsequently accepted or rejected contingent upon the inter-item correlations. However, it is important to note that most of the CPI scales were not developed rationally; rather, they were derived through empirical criteria keying. Specifically, series of questions which had been derived rationally were administered to sample groups who had been previously assessed for characteristics the scales were initially intended to measure. For example, to be included in the sample group that was given the scale of Responsibility, friends and family would first rate the group member's degree of responsibility. The same process was used for the remaining scales and items that were found to discriminate between the criterion group and normal population were included in the scale.

After the initial scales were developed, items were subjected to cross-validation in order to determine the extent to which the construct being measured could be accurately evaluated. Among the 18 original scales, 13 used empirical criterion keying, four used the rational approach, and the final scale used a combination of the two techniques. The two new scales in the 1987 and 1996/2002 versions used empirical criterion keying to obtain and score items already in the CPI.

Similar to the MMPI, CPI scores are standardized using T-scores, which have a mean of 50 and standard deviation of 10. The original 1957 scales were standardized on a normative sample of 6,000 males and 7,000 females that spanned a wide range of demographic characteristics such as socio-economic status, age, and geographic location. Similarly, the 1996 version of the CPI was standardized on 3,000 participants from each sex selected from the CPI archives to be representative of the U.S. population across a wide array of variables.

To facilitate interpretation of the CPI, the 20 scales are organized so that they associate with the following four domains: observable interpersonal style and orientation (i.e. Social Presence), internal normative orientation and values (i.e. Responsibility), cognitive and intellectual functioning (i.e. Intellectual Efficiency), and role and personal style (i.e. Flexibility). These four domains facilitate interpretation of the CPI in that they help practitioners to organize specific information around the more general domains, as well as incorporate data from other assessments into the CPI. Also, easier interpretation is facilitated by the fact that higher values on the CPI scales represent more favorable qualities while lower values represent more unfavorable ones. The exception to this is the final scale (Femininity/Masculinity) which evaluates traditionally feminine and masculine traits. The three vector scales added by Gough to the 1987 version were organized based on factor analysis to evaluate extraversion-introversion, norm-favoring versus norm questioning, and the extent of self-realization.

The short and most recent version of the CPI (CPI 260) is composed of 260 items. Each scale was derived by taking items that most strongly correlated with the longer scales combined with the strongest correlations for external test behaviors. Furthermore, all items were evaluated for contemporary terminology, cross-cultural relevance, disability-relevant content, and tone. The short version resulted in retention of the original 20 scales as well as the three vector scales added by Gough. Four of the scales were renamed and the final revised scales were found to have strong correlations with the CPI 434 scales. The greatest advantage to the CPI 260 is that it only takes about 25 to 35 minutes to complete, whereas the longer version requires about 45 minutes to one hour to complete.

Psychometric Properties

The reliability and validity of the CPI have yielded favorable results compared to other personality inventories. The overall median reliability was .68 for the CPI 434 and .66 for the CPI 260. The test-retest reliability of the CPI 434 ranged from a low of .51 (Flexibility) to a high of .84 (Femininity/Masculinity). However, it should be noted that the test-retest interval was one year, which is a wide time range between test administrations. Internal consistency for the CPI ranged from a low of .43 (Femininity/Masculinity) to a high of .85 (Wellbeing). The overall median internal consistency was .76 for the CPI 434. Internal consistency for the CPI 260 ranged from a low of .39 (Communality) to a high of .87 (Dominance). Also, the correlations between the CPI 434 and the CPI 260 were favorable ranging from .81 to .97.

Factor analytic research has yielded a two-factor solution for the CPI (Internal Controls and Interpersonal Effectiveness), a five-factor solution for the 1996 revision (Ascendance, Dependability, Conventionality, Originality, and Masculinity/Femininity), and a four-factor solution for the CPI 260 (Interpersonal Effectiveness, Dependability, Originality, and Interpersonal Sensitivity). In a broad sense, the factor structure of the CPI suggests that higher scores indicate personal adjustment and lower scores suggest psychopathology. Also, the CPI has been reported to correlate with most of the Big Five factors of personality: Neuroticism, Extraversion, Agreeableness, Openness to Experience, and Conscientiousness.

While considering the psychometric properties of the CPI, it is important to note that the primary work conducted on validation has been predictive. As such, the CPI is less concerned with attractive psychometric properties of personality traits and more with the utility of the test in making accurate predictions. For example, people with high scores on certain scales are likely to be described in certain ways by those close to them. In this sense, the CPI centers on predicting the types of things individuals say or do when placed in various situations. Taken together, the CPI is not an instrument of traits, but a measure of the probability that someone might characterize the test-taker in a certain way. Many empirical studies have found adequate levels of predictive validity for the CPI.

Cultural Considerations

As previously noted, the CPI was developed using "folk norms" which are thought to have cross-cultural relevance. Such is one reason that the measure has been used in cross-national settings and has been translated into 40 languages. Studies in a diverse array of countries have supported the CPI's validity, even among countries that are relatively different from the United States (e.g. Japan, Taiwan, etc.). Further, cross-cultural research has found the CPI to yield factor structures similar to those found in the United States and has shown it to be useful in making accurate predictions across a variety of cultures (e.g. Greek, Swedish, and Norwegian).

However, research has also indicated that some scales on the CPI are more influenced by ethnicity than others. For example, when contrasted with European American males, African American males reported lower levels of extroversion, anxiety, and cynicism. But among females, scores yielded similar results. Another example of ethnic influence was shown with Native Americans. Specifically, when compared with European American men, Native American men reported lower scores of conventional tendencies and less sensitivity to violated norms. Thus, ethnic differences are an important cultural component to consider while administering and interpreting the CPI.

Although empirical research has shown the CPI to be useful in cross-cultural contexts, much remains unknown regarding the role other cultural variables may play. Variables such as race, socio-economic status, and other demographic variables are in need of further study to evaluate the ability of the CPI to predict certain behaviors in specific cultural contexts. Finally, although knowing that differences in CPI scores differ on some cultural variables is important, it is critical to understand why the scores are different. Future research on the CPI should investigate how CPI scores relate to various scales across cultural contexts, as well as the reason behind these differences.

Dimensional Assessment of Personality Pathology (DAPP)

Amanda ElBassiouny

California Lutheran University

The Dimensional Assessment of Personality Pathology-Basic Questionnaire (DAPP-BQ) is used by clinicians to evaluate and treat personality disorders in adults, 18 years and older. It allows a clinician to create a dimensional personality profile that aids in creating a treatment plan for those who are experiencing a personality disorder, ranging from mild to severe trait issues. Creating personality profiles based on dimensions this way is also in alignment with the current criteria for diagnosing personality disorders put forth by the Diagnostic and Statistical Manual of Mental Disorders V (DSM-V). In addition to providing an overview of the basic components of a personality disorder, it also is measuring affect, cognition, and traits related to interpersonal interactions that could potentially impact one's psychological state (Livesley & Jackson, 2009).

The final report of the Dimensional Assessment of Personality Pathology-Basic Questionnaire provides a clinician with trait scores on 18 scales and also includes more specific information that is necessary for diagnosing and creating a plan for treatment. The 18 scales can be grouped into four factors: emotional dysregulation (measured by affective lability, anxiousness, cognitive dysregulation, identity problems, insecure attachment, oppositionality, submissiveness), dissocial behavior (measured by callousness, conduct problems, narcissism, rejection, and stimulus seeking), social avoidance (measured by intimacy problems, low affiliation, and restricted expression), and compulsiveness (measured by compulsivity). It also includes other dimensions, measured by self-harm and suspiciousness (Livesley & Jackson, 2009; Livesley & Larstone, 2008).

This assessment takes approximately 35 minutes to 50 minutes to administer through an online system. The Dimensional Assessment of Personality Pathology-Basic Questionnaire includes 290 items that individuals would respond to on a 5-point Likert scale that ranges from 1 meaning strongly disagree to 5 meaning strongly agree. A report of the data is generated upon completion of the assessment and includes both raw and standardized scores that are compared to general and clinical populations, graphs of the results, details about the scales, and indices. Lastly, the Dimensional Assessment of Personality Pathology-Basic

Questionnaire also includes a validity scale that aims to ascertain if a person is answering based on social desirability or impression management (Livesley & Jackson, 2009).

The Dimensional Assessment of Personality Pathology-Basic Questionnaire has been established to be a valid and reliable measure of personality pathology. In both general and clinical samples, internal consistency reliabilities for the 18 scales ranged from .84 to .95. Furthermore, the Dimensional Assessment of Personality Pathology-Basic Questionnaire was found to have convergent validity with similar measures of personality pathology, assessments of normal personality, self-report measures of personality, and interviews that rated personality (Livesley & Jackson, 2009).

The Dimensional Assessment of Personality Pathology-Basic Questionnaire has allowed clinicians to clearly define and treat personality disorders, but has done so with more precision since this assessment provides greater distinctions among personality disorders. Therefore, it allows clinicians to clearly identify and diagnose a personality disorder that could have many overlapping symptoms with another personality disorder. By having more confidence in the diagnosis, people receiving these results about themselves will gain greater understanding of their past behaviors and can predict, and hopefully fix, any issues in the future they may have. In addition to diagnosing personality disorders, the Dimensional Assessment of Personality Pathology-Basic Questionnaire has had success in assessing anxiety disorders, mood disorders, eating disorders, substance use disorders, and somatization disorders (Livesley & Jackson, 2009).

The DAPP-SF is a short form version of the Dimensional Assessment of Personality Pathology-Basic Questionnaire. The DAPP-SF includes 136 of the original 290 items of the DAPP-BQ. Based on studies with community samples, the DAPP-SF retained the same factor structure as the DAPP-BQ and was found to be reliable. Additionally, the scales of the basic questionnaire and the short form version were found to correlate highly with each other (van Kampen, de Beurs, & Andrea, 2008).

Eysenck Personality Questionnaire-Revised

Alexandros Maragakis

Eastern Michigan University

Eysenck's PEN Model of Personality

Before describing the Eysenck Personality Questionnaire-Revised (EPQ-R), a brief understanding of the theory in which it is based is required. Eysenck proposed that a theory of personality must be based on more than just heuristic traits or psychometric approaches, but should be based in a general theory and provide a nomological network that permits for hypothesis testing. To this extent, Eysenck theorized that human temperament could be captured in a system involving four levels. The first level involved singly occurring acts or cognitions, which could involve talking to a friend on a particular occasion. Behaviors occurring on this first level are highly changeable across time and situation. The second level was composed of habitual acts or cognitions, which could involve speaking with friends on multiple occasions. The third level involved "traits" like sociability and one's ability to communicate and interact with friends, which were defined as significant intercorrelations between different habitual behaviors. The final level consisted of "superfactors" or personality types, like extraversion, which involved substantial intercorrelations between traits. These personality types are highly stable, and unlikely to change.

Within this theory, Eysenck identified three orthogonal personality types: Psychoticism, Extraversion, and Neuroticism (PEN). Psychoticism was defined by traits which included aggression, coldness, egocentrism, impulsivity, lack of empathy, tough-mindedness, and being antisocial. Extraversion was defined by the following traits: sociable, lively, active, assertive, sensation-seeking, carefree, dominant, and venturesome. Finally, neuroticism was defined by the following traits: anxious, depressed, guilt feelings, low self-esteem, tense, irrational, shy, moody, and emotional. According to Eysenck, these personality types were more than just behavioral responses, but were based on an individual's physiological and biochemical structure. Furthermore, these types would be

consistent cross-culturally and ethnically. Together, these factors were the foundation of Eysenck's PEN model of personality.

History and Development of the Eysenck Personality Questionnaire

The EPQ-R has a long history of development and refinement that mirrored the increased sophistication of the PEN model. Originally published as the Maudsley Medical Questionnaire in 1952, it contained 40 yes/no items, and simply focused on neuroticism as a factor (i.e. 20 or more "Yes" responses indicated a higher than average neuroticism factor). In 1959, a 48-item assessment, the Maudsley Personality Inventory, was published. This was the first assessment to assess for both the E and N scales. In 1968, the Eysenck Personality Inventory (EPI) expanded the scales, and the assessment involved 57 yes/no items that captured the E and N scales. Both the E and N scales included 24 questions, and a Lie (L) scale that assessed an individual's attempt to present themselves in a socially desirable way made up the remaining nine questions.

Individuals' scores on the EPI were plotted on a circular graph divided into four quadrants with Extravert/Introvert constituting one end of the plot and Neurotic/Stable constituting the other end. Scores closer to the outside of the circle indicated a more marked personality trait. A score of five or higher on the L scale indicated that participants were presenting themselves in a more favorable light, and may not have been honest while taking the EPI.

The P scale was not included within the assessments until 1975, when the 90-item Eysenck Personality Questionnaire (EPQ) was published. However, criticisms of poor psychometric properties of the P scale quickly arose. Specifically, criticisms of the P scale in the EPQ consisted of low internal reliability (although test-retest reliability was within an acceptable range), low range of scoring, and grossly skewed distribution of the scores.

The Eysenck Personality Questionnaire-Revised (EPQ-R) was developed as a response to criticisms concerning the psychometric properties of the P scale in the EPQ. The new scale consisted of 100 items in a yes/no format: 32 items for the P scale, 23 items for the E scale, 24 items for the N scale, and 21 items as a L scale. The administration time using the EPQ-R is around 20–35 minutes, and it can be scored by hand or through test agencies.

As can be noted, each new version of the EPQ was associated with an increase in the total number of items. This expansion can be accounted for by the additions of new dimensions (the P and L scales), and the psychometric principle that greater length enhances reliability, which was particularly important given the psychometric issues of the P scale. However, given this increase in length, some have expressed concerns with the utility of the assessment in research and clinical settings.

In response to these concerns over length, the EPQ-R Short Scale (EPQ-RS) was created. The EPQ-RS consists of 48 yes/no items, and includes 12 items for each of the P, E, N, and L scales. This version takes about half the time to administer (10–25 minutes) and can be easily scored by hand (usually within one minute). However, this reduction in total questions to reduce the time needed to administer and score the assessment has led the EPQ-RS to psychometric issues, particularly with the P scale.

Psychometric Properties

Validity of the P, E, and N scales has been discussed and examined for over 50 years. Originally derived from item and factor analyses from other personality inventories, the three scales are considered to have high construct validity (i.e. they are highly correlated with the factor they are said to measure and not with other factors). An emphasis on the validity of the superfactors in the PEN theory has been examined throughout its history.

Empirical findings in regard to the psychometric properties of the EPQ-R indicate an improvement compared with previous versions. In particular, the internal reliability, range of scoring, and distribution of the P scale are improved using the EPQ-R. Internal consistency reliability estimates range from .73 to .81 for P, 0.85 to .90 for E, and 0.85 to 0.88 for N. These reliability estimates have proven to be consistent across numerous studies.

Factor analytic studies have indicated a three to four factor structure of the EPQ-R, depending on whether or not the L scale questions are included. Multiple studies, using multiple methods of factor analyses (e.g. alpha factoring, generalized least squares, and maximum-likelihood method), confirm the theoretical P, E, and N superfactor structure of the EPQ-R. The total variance captured by these factors has ranged from 66% to 75% of the data.

Cultural Considerations

Cultural utility has been a key research focus of the EPQ. It was hypothesized that Eysenck's theory of personality traits, particularly the P, E, and N scales, would be universal across cultures given that its basis is founded on the physiological and biochemical structure of an individual and not just a set of arbitrary behaviors. To test this hypothesis, the EPQ has been translated into multiple languages, and has been used in research across many countries and cultures.

The primary methodology used in testing the universality of the EPQ scales has been the use of exploratory factor analysis (EFA). In a study looking at datasets from 34 different countries, data indicated that the four factors (P, E, N, and L) were strongly replicable across all 34 countries, and that there was a significant degree of factorial similarity in comparison to the U.K. sample that was used as the target population in the analyses. This study, along with others, provides evidence that the EPQ and the theory on which it is based may have utility across multiple cultures.

The EPQ-RS has also been tested across multiple countries and cultures (e.g. German, Greek, Hindu). Consistently, the EPQ-RS has been found to have satisfactory psychometric properties (e.g. internal reliability, test-retest reliability, and inter-item correlations) for the E, N, and L scales. However, the data for the P scale has consistently yielded poor psychometric properties. The poor psychometric properties of the P scale may be a function of the reduced number of questions used in the short form.

Conclusion

Taken together, the EPQ-R is a personality assessment that was created from a theory of personality based on decades of empirical research. While it has some limitations, particularly the psychometric properties of the P scale, it is a widely used and well-regarded measure of

typical personality. It is a measure that is highly versatile and can be used in both the research and clinical setting across multiple cultures and countries. In its various forms (i.e. EPQ-R/EPQ-RS), it can meet the demands of nearly any setting, and provide a well-established assessment of personality.

Millon Clinical Multiaxial Inventory (MCMI)

Jennifer Andrews and Sara Bender

Central Washington University

The History of the MCMI-IV

Millon asserted that there are four elements of personology: theory, taxonomy, measurement, and intervention. He explained his ideas in detail in his book *Modern Psychopathology*, which was published in 1969. Through the publication of his text, Millon inspired a reconceptualization of the very nature of personality. His theory eventually generated a classification of personality prototypes and personality disorders.

In 1977, Millon published the first edition of the Millon Clinical Multiaxial Inventory. The original purpose of that test was to aid clinicians in identifying and treating disordered personality. In line with Loevinger's test construction and validation strategy, Millon first developed test items based on how well their content aligned with his theory specifically, rather than the professional nomenclature of the day. He developed a pool of 1,100 test items, which he split in half into two equivalent forms and administered to clinical patients and clinicians to test for internal validity. From the original pool, a final set of 175 items was established and validated.

Within his theory, Millon described three polarity structures that align with the identified evolutionary processes, which he viewed as "universal motivating aims." These aims include pain-pleasure (survival) polarity, active-passive (adaptive) polarity, and self-other (replication) polarity. From one's status on each of these polarities, Millon purported, conclusions may be drawn regarding one's functional (F) and structural (S) domains of personality, which are expressed via traits or disorders. These polarities and the balance or predilection toward one polarity describe the motivating factors that cause the development of an individual's personality function. The assessment scales provided within the MCMI are an operational measure of the resulting enduring personality characteristics. The MCMI-I contained 11 personality scales and nine clinical syndrome scales. In 1987, the MCMI was revised to better reflect the content of the Diagnostic and Statistical Manual (DSM-III-R). The MCMI-II consisted of 13 personality scales, four validity scales, and nine clinical syndrome scales.

Millon conceptualized his instruments as fluid, indicating a desire to revise them whenever progress within the field or a development in theory occurred. In the 1980s and 1990s, a resurgence in the scientific interest pertaining to personality transpired. Great growth occurred within the International Society for the Study of Personality Disorders, as did the popularity of the *Journal of Personality*. Additionally, hundreds of empirical journal articles and book chapters regarding the subjects of personality development and functioning resulted. Simultaneously, the fourth edition of the Diagnostic and Statistical Manual (DSM-IV) was developed as well. Collectively, these events inspired Millon to revise the MCMI again. The MCMI-III, which was published in 1994, eliminated specific personality scales and introduced two scales: Clinical Personality Pattern (Depressive) and Clinical Syndrome (Post-Traumatic Stress Disorder). Additionally, 95 items from the MCMI-II were replaced by 95 newly-developed MCMI-III items, which were said to increase the correspondence in nomenclature between the MCMI-III and the DSM-IV criteria as well as better reflect recent generalization studies. Finally, items were added to strengthen the interpretive report information regarding child abuse, anorexia, and bulimia.

MCMI-IV

Released in the fall of 2015, the MCMI-IV is the most recent edition of the Millon Personality Inventory. The MCMI-IV is an objective personality assessment instrument that aligns closely with the DSM-5 classification system. It is a 195-item test in a true-false self-report assessment, which may be completed in 25 to 30 minutes. Scores are normative for an adult inpatient and outpatient sample. As such, it is to be administered in a clinical setting, and results associated with those within the general population (a non-clinical setting) may not be valid.

The MCMI-IV differs from previous versions of the assessment in several ways. First, the MCMI-IV attends to the individual's response patterns across domains to provide a more holistic description of his or her personality style. The MCMI-IV identifies 15 personality prototype spectra with each prototype existing on a continuum from adaptive to maladaptive. As a consequence, assessment results not only highlight psychopathology, but now also serve to describe aspects of personality. This places any assessed syndrome in the context of an individual's personality styles or disorder. Furthermore, examining scores across the different domains can assist the clinician in forming treatment strategies by facilitating understanding of underlying motivations, allowing for the targeting of specific areas, and identifying which techniques to use for therapy.

Second, the terminology used in the MCMI-IV was updated to better reflect the nomenclature associated with the DSM-5, which was released in 2013. For example, the *thought disorder scale* is now the *schizophrenic spectrum*, reflecting a greater emphasis on the complete DSM criteria for schizophrenia, which not only highlights cognitive abnormality, but also addresses social withdrawal, emotional discontrol, and behavioral abnormalities. Similarly, the *depressive personality scale* was renamed the *melancholic spectrum*. This change differentiates the personality spectrum from the clinical syndrome previously described as dysthymia in the DSM-IV-TR, which is known as persistent depression and

chronic major depression in the DSM-5. The renaming of the personality scale to melancholic spectrum also allows for the expression of the full range of the personality characteristics from mild pessimism to the abnormal level (forlorn), to the severely dysfunctional melancholic level.

Another change in the assessment tool is the inclusion of updated test items. The MCMI-IV adds new response categories to identify pertinent information for secondary screening or referrals. There are response items for Adult ADHD, autism spectrum, violence potential, prescription drug abuse, self-injurious behavior, tendency toward vengeful behavior, and traumatic brain injury. Additionally, since the release of the MCMI-III, Millon developed an additional personality spectrum called the *turbulent spectrum*. At one end of this spectrum, the terms 'ebullient' and 'exuberant' denote a disposition toward high spirits and joyfulness with a desire to engage with the world. On the more extreme end of the spectrum, this personality spectrum shifts from the range of joyous ebullience through the more scattered exuberance, to the level of dysfunction displayed in the turbulent end of the spectrum, which is consistent with tempestuousness and frenetic loss of control. There are several items within the MCMI-IV that reflect this new spectrum.

Scoring

The MCMI-IV scoring can be web-based, software, or completed via the mail. Results may be presented in either an interpretive or a profile report. The interpretive reports align with the DSM-5 and the ICD-10 with the test results designed to integrate with therapeutic practice and the assessment results linked to treatment goals. The interpretive procedure is to first check validity scales, which serve to check for distortions in responses. Elevated scores on the desirability or debasement index can reveal a bias affecting the clinical and syndrome scale scores. The next step is to check for positive responses on noteworthy items, which are the red flags reflecting critical information such as possible traumatic brain injury or violence. Next, the personality scales are reviewed with emphasis on scores in the severe range and then the Grossman facet scales, followed by the clinical syndrome scales. Finally, the data is integrated for the overall profile in the context of presenting issues.

Scores are Base Rate scores rather than T-scores, meaning they are based on the prevalence rate of a disorder and they describe where a person is on a spectrum. In this way, the MCMI differs from other personality assessment tools. The MCMI Base Rate scores compare raw scores of the patient to scores of other patients, unlike other personality tests, which compare scores to non-clinical populations. A score of 60–74 indicates normal style, likely with some traits which may be problematic for the individual. A score of 75–84 indicates an abnormal trait level with more defined dysfunction possible while a score of 85 or more indicates a clinical disorder and likely an impairing level syndrome.

Results

Beyond the basic personality architecture measured in the personality prototype spectra scores, Millon's evolutionary theory specifies eight domains, four functional and four structural, representing the expression of personality in facets aligned with traditional psychological schools of thought. From these eight domains arise the Grossman Facet Scales,

which measure the functional domains: expressive emotion, interpersonal conduct, cognitive style, intrapsychic dynamics, and the structural domains: self-image; intrapsychic content; intrapsychic architecture, and mood/temperament.

While the acute clinical disorders are not derived from Millon's theory, they may be confirmed via the MCMI. Within this assessment, there are ten clinical scales, which align with the diagnostic changes reflected in the DSM-5 and the ICD-10. Three of the scales reflect severe clinical syndromes (noted to have a more psychotic component), including SS schizophrenic spectrum (previously thought disorder), CC Major Depression, and PP Delusional. The remaining clinical scales, each reflecting a separate syndrome, are: (A) Generalized Anxiety, (H) Somatic Symptom, (N) Bipolar Spectrum, (D) Persistent Depression, (B) Alcohol use, (T) Drug use and (R) Post-Traumatic Stress.

The personality scales derive directly from Millon's theory of personality. The scales describe each personality pattern on a broad range from normal to abnormal to clinical disorder. The scales identify and measure characteristics of 15 personality styles/disorders:

- Retiring/schizoid,
- Eccentric/schizotypal,
- Shy/avoidant,
- Pessimistic/melancholic,
- Cooperative/dependent,
- Sociable/histrionic,
- Exuberant/turbulent
- Confident/narcissistic,
- Suspicious/paranoid,
- Nonconforming/antisocial,
- Assertive/sadistic,
- Capricious/borderline,
- Conscientious/compulsive,
- Skeptical/negativistic,
- Aggrieved/masochistic.

An example of a personality spectrum as identified in the MCMI-IV is the "AASchd " spectrum, which describes the Apathetic normal style/Asocial abnormal type/Schizoid clinical disorder spectrum. This spectrum demonstrates the MCMI-IV's ability to capture the full range of personality characteristics from normal to abnormal through the severe level of the clinical disorder. There are three spectrums, which indicate severe personality pathology: ESSschizoph – eccentric/schizotypal/schizophrenic, UBCycloph – unstable/ borderline/cyclophrenic, and MPParaph – mistrustful/paranoid/paraphrenic. These three spectrums are the most severe of the personality disorders and the labels reflect the diagnostic system changes in the DSM-5.

Validity and the Modifying Indices

The MCMI-IV has a validity index consisting of three items that detect random or deviant responses. If two or more of these items are marked true, then the test is invalidated. In addition, there are three modifying indices, the disclosure index (scale X), desirability

index (scale Y), and debasement index (scale Z). The disclosure index measures whether an individual's responses are candid and open. The desirability index measures the degree to which the responder is attempting to appear favorable and the debasement index measures whether the responder is attempting to appear emotionally unwell. When reviewing assessment results, these scores provide an initial validity check for the entire assessment. Excessive omissions and double marked responses will also invalidate the instrument.

Strengths and Weaknesses

Unlike many other personality assessments, each edition of the MCMI is anchored in theory and its results are validated by numerous empirical studies. Another strength associated with the MCMI is its brevity. With only 175 items, the MCMI is much shorter than most personality assessments, allowing patients to complete it in a timely manner and thus minimizing the likelihood of fatigue. Given that it was developed for those with an eighth-grade reading level, most patients find the assessment manageable, which also helps to reduce patient resistance. Despite its length, the MCMI still provides a large quantity of information regarding a wide range of clinically relevant behavior. Finally, the MCMI-IV reflects the criteria and vocabulary utilized in both the DSM-5 and ICD-10 thus linking theory into current systems of treatment planning and psychotherapy.

A drawback of the MCMI is that Millon has produced multiple editions of the test in a relatively short period, resulting in a lack of current research on the most recent version. The MCMI-IV incorporates dramatic changes and these changes may affect the effectiveness of the assessment tool for clinical use. Another complaint is that the scoring for the MCMI is overly complex beyond what is necessary for useful results.

Minnesota Multiphasic Personality Inventory (MMPI)

Andrea L. Barbian-Shimberg

Liberty University

Introduction

The Minnesota Multiphasic Personality Inventory (MMPI) is a widely used psychological test that aids clinicians in assessing personality traits, detecting and diagnosing psychopathology, and selecting appropriate treatment methods. Multiple forms of the MMPI have been adapted from the original version for use with various populations (i.e. adolescents, adults, ethnic groups) in a variety of settings (i.e. personnel screening, correctional facilities, inpatient mental health settings). Additionally, the MMPI is often used in legal proceedings to determine an individual's competence to stand trial or as evidence during the trial.

Historical Overview

The original version of the MMPI was published in 1942 by clinical psychologist Starke R. Hathaway and neuropsychiatrist J. Charnley McKinley in an effort to provide a routine assessment for psychopathology in adult patients at the University of Minnesota Hospital. Hathaway and McKinley sought to create a measure that was more efficient than and would strengthen previous self-report personality inventories. Previous inventories were criticized for (1) failing to validate how individuals actually responded to items, but rather focusing on the researcher's anticipated response; (2) using items that were too transparent and whose intent was easily understood by respondents; and (3) failing to assess whether or not individuals had manipulated their responses (Weiner & Greene, 2017). Hathaway and McKinley were also interested in an instrument that could be used to assess an individual's symptomology over time, by being administered at multiple points throughout the treatment process (Gotts & Knudsen, 2005). Ultimately, Hathaway and McKinley wanted to create a single, empirically based inventory that would allow for the assessment of wide range of significant behaviors, as opposed to multiple, highly specific independent tests.

When developing scale items for the MMPI, Hathaway and McKinley relied exclusively on an empirical approach without a theoretical rationale. Initially, the frequency of "true or false" responses of criterion groups was compared to those of normative groups. If the frequency response difference for the two groups being compared was at least twice the standard error of the proportion of true/false responses, the item was tentatively selected (Weiner & Greene, 2017). Items were then eliminated if the frequency of the criterion group's response was less than 10% or responses to an item appeared to reflect a bias in regard to marital status or socio-economic status. Therefore, a person's score reflected how many items they answered in the same manner as the criterion group. This type of scoring removed prior assumption regarding the relationship between the individual's behavior and their self-report response.

The original version of the MMPI contained a total of 550 items and was composed of 10 clinical scales and four validity scales. The first 10 rows of Table 1 present a summary of the 10 clinical scales, which were displayed as numbers and abbreviations (see left column of Table 1), by including their clinical manifestation (see center column of Table 1) and a brief description corresponding to the characteristic features assessed by the clinical scale (see right column of Table 1): scale 1 (Hs) measured for hypochondriasis (i.e. the individual's level of concern and preoccupation with their bodily symptoms, overall health, and complaints), scale 2 (D) measured for depression (i.e. the respondent's level of happiness and symptoms of clinical depression including poor morale, dissatisfaction with life, and lack of hope), scale 3 (Hy) measured for hysteria (i.e. the respondent's level of emotional wellness, vulnerabilities, neuroticism, cynicism, and shyness), scale 4 (Pd) measured for psychopathic deviate (i.e. level of maturity, social interaction, response to authority, level of alienation, aggressiveness, and social maladjustment), scale 5 (Mf) measured for masculinity-femininity (i.e. interest in or conformity to stereotypical gender roles including vocations, hobbies, preferences, and sensitivities), scale 6 (Pa) measured paranoia (i.e. respondent's level of sensitivity or suspiciousness, and moral self-righteousness), scale 7 (Pt) measured for psychasthenia (i.e. respondent's level of compulsiveness, abnormal fears, anxiety, worry, self-criticism, and difficulty concentrating), scale 8 (Sc) measured for schizophrenia (i.e. the respondent's bizarre thoughts, level of disorganized thought, impulse control, social and familial relationships, and disturbing questions of self-worth and identity), scale 9 (Ma) measured hypomania (i.e. respondent's degree of excitement, level of mood stability, thought and behavior patterns, and overactivity), and finally, scale 0 (Si) measured for social introversion (i.e. the respondent's level of introversion vs. extroversion and limited social skills) (Ball, 1962).

In addition to the clinical scales, the original version of the MMPI contained four validity scales which were designed to measure the respondent's test-taking ability. The last four rows of Table 1 present a summary of the four validity scales, which were displayed as abbreviations (see left column of Table 1), by including their clinical manifestation (see center column of Table 1) and a brief description corresponding to the characteristic features assessed by the validity scale (see right column of Table 1). The (?) or "Cannot Say" scale assessed for excessive omission, which hindered meaningful interpretation of the inventory. The (L) scale or lie scale was used to determine the degree to which the respondent was trying to paint him or herself in an unusually positive light. Therefore, a high (L) score indicated that the respondent was "faking good" (Ball, 1962). Furthermore, the (F) scale was

Table 1 Original MMPI Scales

Scale No. Abb.	Clinical manifestation or description	Description of the characteristic features assessed by the scale (number of items in scale)
1 Hs	Hypochondriasis	Level of concern and preoccupation with one's bodily symptoms, health or health issues (32)
2 D	Depression	Level of happiness and presence of depressive symptoms (57)
3 Hy	Hysteria	Level of emotional wellness, awareness of problems, vulnerabilities (60)
4 Pd	Psychopathic deviate	Level of maturity, social interactions, aggressiveness, conflict (50)
5 Mf	Masculinity-Femininity	Interest in or conformity to gender stereotypes (56)
6 Pa	Paranoia	Level of sensitivity or suspiciousness (40)
7 Pt	Psychasthenia	Level of compulsiveness, feelings of fear and/or inferiority, worry (48)
8 Sc	Schizophrenia	Level of disorganized thought, social and familial relationships, thoughts and perceptions (78)
9 Ma	Hypomania	Level of mood stability, thought and behavioral patterns, degree of excitement (46)
0 Si	Social introversion	Level of introversion or extroversion, social skills (69)
?	Cannot say scale	Number of omitted responses
L	Lie scale	Degree to which one attempted to "fake good"
F	F Scale	Degree to which one attempted to "fake bad"
K	Correction scale	Measure of test-taking attitudes and dissimulation

developed to measure the opposite, the degree to which the respondent was attempting to paint him or herself in an unusually negative light. A high (F) score indicated that the respondent was "faking bad" (Ball, 1962). Finally, the (K) scale or correction scale was used to provide a measure of test-taking attitudes and recognize dissimulation. Respondents were given the test individually or as groups and were asked to respond in a true/false fashion. Standard scores were derived for the 10 clinical scales of the original MMPI. The normative population responded with responses ranging from 45 to 54, and are therefore considered non-elevated responses (Ball, 1962). A score above 70 would be considered indicative of pathology, as it is two standard deviations above the mean of the normative adult population (Ball, 1962).

Changes to the MMPI Over Time

As use of the MMPI increased and cultural norms shifted over decades, the need for revisions became apparent. The first revision of the MMPI occurred in the 1980s and resulted in publication of the MMPI-2 in 1989. In 1992, the MMPI-A (Adolescent) was published in

an effort to construct scales that were specific to the adolescent population. Finally, the newest form of the MMPI, the MMPI-2-RF (Restructured Form), was published in 2008 in an effort to revise scale items that were problematic psychometrically due to scale heterogeneity and excessively high scale intercorrelations (University of Minnesota Press, 2015). Table 2 provides an overview comparison of the MMPI, MMPI-2, MMPI-A, and MMPI-2-RF in terms of authors, date published, age range, reading level, administration formats, completion time, number of items, response format, scales, and norms. Table 3 provides a

comparison of scales in various adaptations of the MMPI appearing in the MMPI-2, MMPI-A and MMPI-2-RF.

Development of the MMPI-2

As of the late 1950s, the MMPI had become one of the most widely used personality inventories. The use of the MMPI expanded beyond hospital settings and into general medical settings, correctional settings, and military and public safety evaluations. As a result of its growing use, re-standardization was needed to reflect an inventory that was representative of the United States population, contained updated item content, and provided for appropriate representation of different genders, religious views, and ethnic backgrounds (see Table 2). The goal of the re-standardization process was to maintain continuity of the test while making the needed improvements. In 1989, the MMPI-2 was published by James N. Butcher, A. Grant Dahlstrom, John R. Graham, and Auke Tellegen (University of Minnesota Press, 2015; Weiner & Greene, 2017).

With the development of the MMPI-2 came a newly developed item pool containing content scales, content component scales, personality psychopathology five scales, and restructured clinical scales (see Table 3). The clinical scales (hypochondriasis, depression, hysteria, psychopathic deviate, masculinity-femininity, paranoia, psychasthenia, schizophrenia, mania, and social introversion) remained the same as with the original version of

the MMPI. The content scales focused on moving toward uniformity and a content cluster approach including four themes: internal symptoms, external or aggressive tendencies, a devalued view of self, and general problem areas. The content scales include anxiety, fear, obsessions, depression, bizarre mentation, anger, cynicism, antisocial practices, type A, low self-esteem, social discomfort, family problems, work interference, and negative treatment indicators. The clinical subscales include the Harris-Lingoes subscales and social introversion subscales. The Harris Lingoes subscales were created to help with profile interpretation in order to determine if a diagnosis is necessary.

The supplementary scales screen for anxiety, repression, ego strength, dominance, social responsibility, college maladjustment, post-traumatic stress disorder (PTSD-Keane), marital distress, hostility, over-controlled hostility, gender role-masculine, gender role-feminine, addiction admission, addiction potential, and the MacAndrew Alcoholism Scale Revised (MAC-R). Additionally, the MMPI-2 contains the PSY-5 scales: aggressiveness, psychoticism, disconstraint, negative emotionality, and introversion/low positive emotionality. Revised clinical scales include demoralization, somatization, low positive emotionality, cynicism, antisocial behavior, persecutory ideas, dysfunctional negative emotion, aberrant experiences, and hypomanic activation. Validity scales include cannot say, variable response consistency, true response consistency, infrequency, back infrequency, infrequency psychopathology, lie, correction, and superlative.

In the re-standardization process, the committee deleted various items due to content, and reworded items to reflect current language that was easily understood and not sexist. Additionally, a new normative sample was obtained to reflect a national representative of the United States in regard to age, marital status, ethnicity, education, and occupation status. The MMPI-2 also reflects a newly developed item pool containing the following scales: content scales, content component scales, personality psychopathology five scales, and restructured clinical scales. Finally, where the MMPI could be used with all ages, the MMPI-2 is only to be used with adults over the age of 18. The MMPI-A was developed for use specifically with the adolescent population.

Development of the MMPI-A

Initially, the MMPI was designed for use with individuals over the age of 16 (see Table 2). Early on the MMPI was used to detect, diagnose, and plan treatment for delinquent adolescents (Gotts & Knudsen, 2005). However, this posed a number of challenges regarding normative data sets, appropriateness/relevance of item content for a younger population, and the absence of scales developed specifically for the assessment of adolescent development and psychopathology (University of Minnesota Press, 2015). Following initial studies of the use of the MMPI with adolescents, Hathaway and Monachesi performed a longitudinal/prospective study of approximately 15,000 adolescents. In their data collection, Hathaway and Monachesi considered school records, input from teachers regarding students' difficulties, and scores on vocational and intelligence tests, with the intent of identifying MMPI predictors that could indicate risk factors for the development of delinquent behaviors (Gotts & Knudsen, 2005). As a result, multiple normative data sets for adolescents were developed, of which the most frequently used are those by Marks and Briggs (1967). The development of the MMPI-A has provided valuable data for

various topics ranging from prediction of juvenile delinquency to identifying personality precursors of schizophrenia (Gotts & Knudsen, 2005). Additionally, the MMPI-A-RF was published in 2016 with non-gendered norms derived from the MMPI-A normative sample.

As seen in Table 3, in addition to the original 10 clinical scales and PSY-5 scales, the MMPI-A includes similar validity scales, with the exception of back infrequency (F_B) and superlative (S) and the addition of infrequency 1 (F_1) and infrequency 2 (F_2). The Harris-Lingoes subscales are also used in MMPI-A. The most notable differences lie in the content and content component scales. The items are written in a manner that make them relevant and useful for individuals under the age of 16. Additional items focus on conduct, antisocial behaviors, competitiveness, isolation, achievement, and peer group interactions (see Table 3).

Development of the MMPI-2-RF

As previously noted, the MMPI-2-RF (Restructured Form) was developed in part in an effort to revise scales by addressing scale heterogeneity and those with excessively high scale intercorrelations, as they had been identified as psychometrically problematic. The MMPI-2-RF was published by Auke Tellegen and Yosef S. Ben-Porath in 2008. While the MMPI-2-RF maintained continuity with the original MMPI, Tellegen and Ben-Porath created Restructured Clinical (RC) Scales. The MMPI-2-RF uses 60% of the MMPI-2 item pool and the same normative data from 1989. The biggest changes are seen in the alteration of validity scales of the MMPI-2. While the methodology used to develop the MMPI-2-RF has been both criticized and defended, some argue that the MMPI-2-RF is a new test, rather than a revision of the MMPI-2 (University of Minnesota Press, 2015).

As seen in Table3, the most recent revisions to the MMPI based on changes included restructuring of the MMPI-2 to the MMPI-2-RF. The number of items dropped from previous versions of the MMPI to approximately 300 (see Table 3). The scales in the MMPI-2-RF include validity scales, restructured clinical scales, PSY-5 scales, higher-order scales, somatic/cognitive scales, internalizing scales, externalizing scales, interpersonal scales, and interest scales. The changes reflected in the MMPI-2-RF are linked conceptually and empirically to modern theories and models of personality, as well as psychopathology.

Administrating, Scoring, and Interpreting the MMPI

The various forms of the MMPI (MMPI-2, MMPI-A, MMPI-2-RF) are self-report inventories that can be administered through various methods including paper and pencil, online, or on the computer. The accuracy of the respondent's self-report is influenced by their motivation to provide an accurate self-report and their awareness and insight into their thoughts, behaviors, and emotions (Butcher, Haas, Greene, & Nelson, 2015). Scoring on the MMPI can be done by hand or on the computer, either directly if taken on the computer or

through the responses being entered into the computer. Hand scoring of the MMPI is generally discouraged as it is prone to error and is extremely time consuming (Weiner & Greene, 2017). There are a number of factors to consider when assessing the validity of the administration of the MMPI. First, the clinician must consider the respondent's item omission. Generally speaking, as the number of items omitted approaches 30, for all versions, the results become more uninterpretable (Weiner & Greene, 2017). Second, the consistency of item endorsement is measured by the Variable Response Inventory (VRIN) and True Response Inventory (TRIN) scales. Finally, accuracy of item endorsement is assessed to determine whether respondents provide self-favorable descriptions of psychopathology or self-unfavorable descriptions of psychopathology.

When interpreting the MMPI, it is important to remember to analyze the scores in the context of the individual respondent. Best practice would suggest that the MMPI is given as part of a battery of psychological tests in order to provide support for pathology and/or diagnosis. Interpretation of the MMPI is based on codetypes, which is the two highest clinical scales elevated to a over 65 or greater. A *spike codetype* refers to a single elevated scale. As codetypes are identified, they can be interpreted to identify various signs of pathology and can be used in conjunction with the DSM-V to diagnosis various mental illnesses. Additionally, an MMPI profile can be compared to different comparison groups (i.e. psychiatric patients, personnel screening applicants, prison inmates, etc.), rather than the standard normative group.

Intellectual and Social Context

Use of the MMPI in Clinical Settings

The MMPI was originally designed by Hathaway and McKinley (1943) for use in clinical settings. The intent was to identify and assess individuals' personality structure for possible pathologies through their self-report. However, discrepancies existed, and continue to exist, between psychological tests and diagnostic classification systems (i.e. Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-V)). A number of research studies have indicated that while the MMPI provides valuable information related to a client's mental health, in and of itself, it is not a sufficient diagnostic tool. While the MMPI alone is not sufficient when making a psychiatric diagnosis, it has been found helpful in aiding clinicians in considering differential diagnoses. Various scales within the MMPI have been identified as predictors of psychiatric disorders such as anxiety disorders, depressive disorders, substance-related disorders, etc. For example, depressive disorders have been found to correlate with the MMPI-2 RF scales Emotional/Internalizing Dysfunction (EID), Demoralization (RCd), Low Positive Emotions (RC2), and Self-Doubt (SFD) (Haber & Baum, 2014). Additionally, anxiety disorders were predicted by responses to scales related to gastrointestinal complaints and other somatic responses (Haber & Baum, 2014). Therefore, the MMPI is widely used in both inpatient and outpatient clinical settings to identify areas of an individual's personality and assess for possible related psychopathologies.

Use of the MMPI in Correctional Facilities and Legal Proceedings

The MMPI has also been used in a variety of ways in the legal environment and has an extensive research base to support its use. For decades, forensic psychologists have used psychological evaluations in personal injury litigation, evaluations of criminal and prison populations, determining the need for psychiatric commitment, the capacity of a parent to provide care to his or her children or be granted custody of children, and in the evaluation of immigrants. With regard to intimate partner violence (IPV), the MMPI-2 has been found to provide an accurate appraisal of the victim's psychological functioning and credibility (Friedman, Lewak, Nichols, & Webb, 2008). Although its use in legal cases differs greatly from its clinical use, the MMPI-2 has been widely accepted as a reliable and valid assessment of an individual's mental health status and personality characteristics in forensic psychology. Additionally, the MMPI-2 can be used with diverse populations and has been shown to be a fair evaluation of minorities and non-English speaking individuals. Interestingly enough, the MMPI-2 is preferred by forensic practitioners over the most recent version, the MMPI-2-RF (Friedman, Lewak, Nichols, & Webb, 2008).

Use of the MMPI for Personnel Screening

Personality evaluations, in addition to background checks, are widely used in employment screening processes. Various employment opportunities require screening for personality structure, possible psychopathologies, and unwanted behaviors. The MMPI is most commonly used in the personnel evaluation of first responders (i.e. police officers, fire personnel, and paramedics), nuclear power plant employees, and various other occupations where fitness for duty must be examined. The MMPI-2 has been widely utilized in the screening of police officer applicants. Applicants are often being screened for antisocial behaviors, drug and alcohol use, and other behaviors often correlated with embezzlement, excessive use of force, tampering with evidence, perjury, misuse of a firearm, accepting bribes, etc. (Butcher, 2006). Additionally, the MMPI has been used in military settings, specifically in screening individuals for acceptance in aviation or special operations positions.

Current Emphasis and Future Directions in Research, Theory, and Methodology

Since its inception, the MMPI has undergone multiple revisions and has been translated into many different languages. One of the most current uses and emphases of the MMPI relates specifically to the use of the MMPI-2-RF with law enforcement. The MMPI-2-RF now offers the Police Candidate Interpretive Report (PCIR) developed by Corey and Ben-Porath (2017). The goal in developing the PCIR for the MMPI-2-RF was to create an easily accessible and evidence based report that provided meaning to a candidate's scores. The overall hope is that the PCIR will enhance the quality and effectiveness of police officers, while decreasing counterproductive behaviors and increasing public trust. Future research related to the MMPI includes following technological developments and electronic

advancements. It is expected that self-report measures will continue to be important and therefore the need for regular evaluation and development of new norms will exist.

Multidimensional Personality Questionnaire

Kristina C. Peterson, Matthew C. Peterson, and Bernardo J. Carducci

Indiana University Southeast

Overview

The Multidimensional Personality Questionnaire (MPQ), developed by Auke Tellegen and colleagues in 1982, is a self-report questionnaire composed of 276 items (2011). This questionnaire has expanded research on the topic of personality from the well-known Myers-Briggs Type Indicator (MBTI) and Minnesota Multiphasic Personality Inventory (MMPI). The MBTI became a quickly popular personality test because it evaluates what is considered a "typical personality" based on the decisions that a person makes, which was seen as more indicative of a person's personality (2016). Conversely, the MMPI is used to measure a person's level of psychopathology present in their personality (Framingham, 2015) which led to the popularization of this inventory being used in a variety of clinical settings (Framingham, 2015). The main objective of the MPQ, however, is to assess normal personality (2011), which is defined as being devoid of psychopathology (Neuman, 2013). This questionnaire uses a dimensional approach (2011), which differs from the previous personality test models because it does not categorize the test taker into a type of personality, but rather describes the extent to which the person exhibits each personality trait (Dimensional models of personality disorders, n.d.).

Previous editions of the MPQ have included both 300 and 198 items, however the current edition has 276 items (Patrick & Curtin, 2002; Multidimensional Personality Questionnaire). There is also a short form available, which consists of 155 items and takes approximately 30–40 minutes to administer (2011).

Test Components

There are 11 primary trait scales used to assess personality within the MPQ. The labels of the primary traits are Well-Being (WB), Social Potency (SP), Social Closeness (SC), Absorption (AB), Achievement (ACH), Alienation (AL), Stress Reaction (SR), Aggression (AG),

Control (CON), Harm Avoidance (HA), and Traditionalism (TRA) (DiLalla et al., 1993). Table 1 provides the descriptions of each of these traits, as well as the number of items included for each.

The MPQ is divided into four higher order traits: Positive Emotionality (PEM), Negative Emotionality (NEM), Constraint (CON), and Absorption (AB) (MPQ Standard 2011). As shown in Table 2, a person that scores high in PEM exhibits behavior of enjoyment in social and work environments. In contrast, people that score high in NEM are likely to experience high levels of anger and anxiety. CON is characterized by a person having the tendency of inhibiting their impulses and not engaging in risky behavior. Lastly, AB is represented by the acceptance of an extremely vivid imagination, including a higher internal sensory experience. Persons that are experiencing this heightened imagination may also have either a "peak experience" or a dissociative effect; this is dependent on additional personality characteristics. These four higher order traits are assessed using the 11 primary trait scales, which then indicate the level of each higher order trait within a person's personality.

As seen in Table 2, the four higher order traits are typically associated with specific primary traits. Positive Emotionality (PEM) is associated with the traits Well-Being, Social

Table 1 The Primary Traits and Description Including the Number of Items of Each Trait Within the MPQ (MPQ Standard 2011)

Primary traits	Description of high scorers
Well-Being (WB) – 23 items	Generally optimistic, feel good about themselves, and enjoy what they do
Social Potency (SP) – 25 items	Persuasive in nature and enjoy being the center of attention
Achievement (ACH) – 20 items	Highly driven, enjoy challenging tasks, and ambitious
Social Closeness (SC) – 21 items	Sociable, generally warm and affectionate, and are comforted by being around others
Stress Reaction (SR) – 23 items	Are anxious, easily upset, and irritable
Aggression (AG) – 19 items	Tendency to be physically aggressive toward others for own enjoyment
Alienation (AL) – 20 items	Prone to thinking others are wishing them harm
Control (CON) – 24 items	Cautious in nature, level headed, and like to plan ahead
Harm Avoidance (HA) – 26 items	Prefer to engage in activities that are not dangerous or tedious
Traditionalism (TRA) – 27 items	High moral standards and have a regard for order and law
Absorption (AB) – 34 items	Tend to be imaginative, engage in "crossmodal" experiences (i.e. synesthesia), and more likely to experience an altered state of consciousness

Table 2 Four Higher Order Traits and Descriptions Including the Primary Traits within each Higher Order Trait (DiLalla et al., 1993)

Higher order traits	Description
Positive Emotionality (PEM) Primary traits: WB, SP, ACH, and SC	**High Scorers:** Prone to experience happiness, and engage in rewarding personal interactions **Low Scorers:** Tend to be joyless, have loss in interests, and exhume depressive disengagement
Negative Emotionality (NEM) Primary traits: SR, AG, and AL	**High Scorers:** Prone to anger, anxiety, and negative emotional / behavioral engagement **Low Scorers:** Tend to remain calm, unemotional, and relaxed
Constraint (CON) Primary traits: CON, TRA, and HA	**High Scorers:** Tendency to avoid risk, refrain from giving into impulses, and do not engage in unconventional behavior **Low Scorers:** Inclined to act on impulses, engage in risky behaviors, and are not impacted by typical social norms
Absorption (AB) Primary traits: AB	**High Scorers:** Tend to be more imaginative and experience altered states **Low Scorers:** Engage in subjective experiences

Potency, Achievement, and Social Closeness. Negative Emotionality (NEM) is assessed with the traits Stress Reaction, Aggression, Alienation, and Absorption. Constraint is indexed by the traits Control, Traditionalism, and Harm Avoidance (DiLalla, et al., 1993).

In addition to the 11 primary trait scales, the MPQ also includes scales that are used to test the validity of the test. The Variable Response Inconsistency (VRIN) and the True Response Inconsistency (TRIN) scales are two of the scales used to test validity within the primary trait scales. The VRIN scale tests consistency between responses of questions that contain similar content, which indicates that the questions should be answered similarly. The TRIN scale contains questions that, if scored in the opposite direction, are similar. Meaning, there is inconsistency if there is an imbalance of "true" or "false" answers (Patrick & Curtin, 2002).

Test Administration

The MPQ is typically administered to a population of, at least, 18 years or older, with a minimum of a 6th grade reading level. The test takes approximately 35–50 minutes to administer, with the short form taking only 30–40 minutes (MPQ Standard 2011).

Reliability and Validity

Reliability is an important aspect of any assessment because it demonstrates the accuracy of the test's findings. This can be evaluated using many techniques, including the popular

inter-item correlation and test-retest correlation. An inter-item correlation is a type of internal consistency evaluation that assesses the relationship between items within an assessment that are designed to test the same thing. The latter, test-retest correlation, assesses the reliability of results from one time to another (Trochim, 2006).

Tellegen and Waller used these techniques to assess the internal consistency and reliability of results for the MPQ. Using four groups of individuals – the first two comprised of male and female college students and the last two comprised of identical and fraternal twins ranging from 18–30 years old – the researchers found that none of the 11 scales fell under an alpha of 0.75 within the inter-item correlation which means that the relationships between the items that are meant to test similar aspects are strong. A one-month test-retest correlation was also evaluated using the college age sample, in which a correlation of 0.89 was found. Which indicates that the reliability of results is also strong (Tellegen & Waller, 2008).

In addition to reliability, validity is also an important aspect of an assessment because it shows that a test is evaluating what it is meant to evaluate (Trochim, 2006). The validity for the MPQ was assessed by comparing it against other well-known self-report personality measures (Tellegen & Waller, 2008). This technique is often used to investigate construct validity (Trochim, 2006). The findings of this evaluation showed that there were many positive correlations between these tests. One such assessment includes the Minnesota Multiphasic Personality Inventory-2 (MMPI-2). The correlation between these tests showed that the MPQ PEM scale was more strongly related to the MMPI-2 depression measure ($r = -.67$) than it was to the MMPI-2 anxiety measure ($r = -.19$), and vice versa which supports Tellegen's PEM-depression/NEM-anxiety model (Tellegen & Waller, 2008).

Conclusion

Overall, the MPQ was developed to identify and explain dimensions of an individual's personality through self-report measures. In evaluating the reliability and validity, it was shown that the developers successfully accomplished their goal. The MPQ could be beneficial in counseling, clinical, and research settings in which the scores could be used to provide feedback that is individualized to the person. The scores obtained through this evaluation could also help an individual to better describe and understand their personality traits, strengths, and weaknesses (Tellegen & Waller, 2008).

Myers-Briggs Type Indicator

Scott P. King and Brittany A. Mason

Shenandoah University

Overview

The Myers-Briggs Type Indicator (MBTI®) is an instrument published by CPP, Inc. designed to determine a respondent's preferences in how they see the world and make decisions, based on four pairings stemming from Carl Jung's theory of psychological types.

It was created by Katharine Cook Briggs and Isabel Briggs Myers with the purpose of making Jung's theory relevant and understandable in people's everyday lives. The instrument aims to identify preferences in respondents' patterns of answers that can then be classified into one of 16 personality types.

Despite widespread use in a variety of organizational settings, the MBTI's psychometric properties have been subject to criticism from academic researchers.

History

Katherine Cook Briggs and Isabel Briggs Myers published the *Briggs Myers Type Indicator Handbook* in 1944 as an effort to help women entering the war-time industrial workforce find jobs suitable for their personalities. Briggs, despite lacking academic affiliation, theorized her own personality typologies that she adapted to fit Jung's after reading his book *Psychological Types*.

Katherine Briggs' daughter, Isabel Myers, developed her own interest in personality types that galvanized with the onset of World War II. Myers had little formal training in psychology or psychometrics, and apprenticed under Edward Hay, a personnel officer in Philadelphia. In 1962, the Educational Testing Service published the MBTI (renamed in 1956) for research purposes only. Mary McCaulley (University of Florida) updated the MBTI *Manual* for its 1985 publication after Myers died in 1980. Myers transferred MBTI publication rights to CPP in 1975, and with McCaulley, founded CAPT as a research laboratory.

Currently, three entities promote the MBTI. CPP is the publisher of the MBTI. CAPT is a not-for-profit research and training center providing numerous resources, including the peer-reviewed *Journal of Psychological Type.* The Myers & Briggs Foundation (2015) provides guidance in accurate and ethical use of the MBTI instrument, and awards biennial "Isabel Briggs Myers Memorial Research Awards." Myers' son, Peter Myers, and his wife, Katharine Downing Myers, currently hold the copyright to the MBTI, which will be passed to the Myers & Briggs Foundation upon their deaths.

According to Cunningham (2013), the MBTI is the most popular personality test in the world, with 2 million people taking it annually, frequently at the request of employers, vocational counselors, or career coaches. Its users include more than 10,000 companies, 2,500 universities, and colleges, and 200 government agencies. As of 2015, 89 *Fortune 100* companies had used it within their organizations.

Purpose, Preferences, and Personality Types

The MBTI is designed to determine respondents' preferences in four opposite pairs known as "dichotomies." Each dichotomy is a division of two mutually exclusive groups, in this case, type preferences, typically referred to with a letter abbreviation: Extraversion (E) – Introversion (I), Sensing (S) – Intuition (N), Thinking (T) – Feeling (F), and Judging (J) – Perceiving (P). Based on these preferences patterns, the instrument categorizes a person into one of 16 personality types, where each type is a combination of the four dichotomies, e.g. INTJ.

The Extraversion/Introversion dichotomy categorizes respondents' preferences in how they focus attention, with "extraverted" people preferring to focus on the external world, and "intraverted" people preferring to focus on the internal world. Briggs and Myers conceptualized this pairing similarly to Jung's attitude-based description of introversion and extraversion as based in the relationship between energy, action, and reflection, with *extraverts* gaining energy from action and losing energy from reflection, and *introverts* losing energy through action and gaining through reflection.

The Sensing/Intuition dichotomy categorizes respondents' preferences in how they absorb information, with people in the "sensing" category taking in information in an orderly, step-by-step fashion, relying on their five senses, while those in the "intuition" category taking in information holistically, seeing it in a wider context. Jung described this set of functions as "perceiving" functions, since they involve how people gather information as they perceive the world.

The Thinking/Feeling dichotomy categorizes respondents based on how they make decisions after taking in information, with people in the "thinking" category preferring to be as objective and rational as possible, and people in the "feeling" category preferring to rely on empathy and inserting themselves into a situation. Jung described this set of functions as "judging" functions. After gathering information through either sensing or intuiting, one uses either thinking or feeling to make a decision. *Thinkers* attempt to detach themselves from the situation and think about it logically and rationally, while *feelers* attempt to see the situation from each side's eyes and make a decision resulting in the best fit for all parties involved.

According to Jung, each person uses one of the above four functions more predominantly than the rest, and the four functions operate together with attitudes of extraversion or introversion, in that each function can be expressed in either an extraverted or introverted way. Briggs and Myers added to these a classification of what function (judging or perceiving) respondents prefer as a lifestyle.

The Judging/Perceiving dichotomy categorizes respondents in terms of how they deal with the world, with people in the "Judging" category preferring to decide on a course of action and carry it out, and people in the "Perceiving" category preferring to continue to take in information before taking action. *Judgers* prefer making decisions and acting on them in an orderly fashion, and *perceivers* prefer to collect all possible information before acting, and remain open to different courses of action.

Thus, when combining one's attitude (E/I), perceiving function (S/N), judging function (T/F), and lifestyle preference (J/P), 16 different personality types are possible: ENTP, ENTJ, ENFP, ENFJ, ESTP, ESTJ, ESFP, ESFJ, INTP, INTJ, INFP, INFJ, ISTP, ISTJ, ISFP, and ISFJ. Briggs and Myers have further theorized that interactions between preferences, what they call "type dynamics," normally develop in such a way that one "dominant" function (S/N/T/F) appears early in life, one "auxiliary" function during adolescence, and one "tertiary" function during midlife, with an "inferior" function (the opposing preference of the dominant) being present in one's unconscious. Which functions assume which roles depends on a person's lifestyle preference (J/P) and attitude preference (E/I).

Formats

According to the Myers & Briggs Foundation, four versions of the MBTI are currently in use: a self-scorable Form M, a standard Form M (administered as MBTI Step I™ by its publisher CPP), Form Q (administered as MBTI Step II™ by CPP), and MBTI Step III™. In any form, the MBTI consists, at a minimum, of a number of forced-choice items asking respondents to choose which of two items they feel best describes them. All forms provide respondents with their four-letter personality type, but the MBTI Step II™ is designed to provide a more nuanced assessment of a respondent's personality, and the MBTI Step III™ is intended solely for use in one-on-one counseling or coaching sessions.

The MBTI Step I consists of 93 items and typically takes about 20 minutes to complete. Scoring the test provides respondents with their four-letter personality type. To administer the test, potential users are required to become an MBTI Certified Practitioner by completing a four-day MBTI Certification Program, or by providing verification of credentials, including a Master's degree or state certification in a psychology-related field. This instrument and manual have been translated into 20 different languages.

The MBTI Step II consists of 144 items and typically takes about 35 minutes to complete. Scoring the test provides respondents with their four-letter personality type, along with more personalized description of their preferences through the use of facets of each type. CPP recommends this version of the instrument for coaching, action planning, and team building. It can be administered by individuals completing the MBTI Certification Program.

The MBTI Step III consists of 222 items and is intended for use in coaching or counseling sessions between a client and a practitioner. It provides respondents with their four-letter

personality type, although in the context of a report written to the client in "non-type" language, designed for exploration through dialogue with a counselor. The Center for Applications of Psychological Type (CAPT®) (2015) requires prospective practitioners of the MBTI Step III to complete their MBTI® Step III Certification Program, in addition to meeting the qualifications of administering the Step I and Step II tests.

Criticisms

Despite its popularity, the MBTI has been subject to criticism from academic psychologists and psychometricians, who attribute its widespread use to aggressive marketing by CPP. Much of the criticism stems from academic research starting in the late 1970s (see 2005 review by David Pittenger in *Consulting Psychology Journal: Practice and Research*) revolving around the MBTI's emphasis on dichotomous (as opposed to continuous) scales, test-retest reliability, predictive ability for career success, factor analytic (see Factor Analysis in Personality Research) structure, convergent validity, and discounting of situational influences on behaviors or cognitions.

Trait theorists disagree with the MBTI's foundation in type theory, the belief that people can be classified dichotomously (e.g. a person prefers *either* extraversion or introversion) instead of viewing personality constructs as a continuous scale between two poles. If people were truly able to be classified dichotomously, then distributions of scores should be bimodal on each preference dimension but trait scores' distributions tend to show most scores clustering near a midpoint. Thus, opponents argue that assuming statistically significant personality differences exist between individuals may not be true for respondents whose scores place them near the midpoint of a preference dimension. Also, several studies have shown test-retest reliability for the 16 MBTI types to be lower than desired.

A common model the MBTI has been compared to in convergent validity examinations is the Five Factor Model (FFM, see Big Five) of personality. Scores from extraversion, openness, agreeableness, and conscientiousness have been shown to have positive correlations with MBTI scores in extraversion (although Jung's definition is somewhat different than modern conceptualizations), intuition, feeling, and judging. The fifth component, neuroticism, has appeared to not overlap with any MBTI preference type – something FFM proponents have criticized, although the MBTI Step III instrument attempts to include this dimension.

The Myers & Briggs Foundation appears to counter the accusation of over-reliance on type in their website's ethical guidelines for administering the MBTI: "Explain how people can and do act in ways contrary to their preferences because of personal history, education, training and experience – and sometimes too because of pressure from family, relationships, job environment, or culture." Other guidelines, such as "Present psychological type as describing healthy personality differences, not psychological disorders or fixed traits" and "The administrator should not counsel a person to, or away from, a particular career, personal relationship or activity based solely upon type information," seem to address criticisms relating to the stability of types, and using the instrument to predict job performance, respectively.

MBTI supporters point to numerous studies supporting the MBTI's utility, validity (see Validity, Issues of), and reliability (see Reliability, Issues of), yet most of those studies have appeared in the *Journal of Psychological Type*, which, while peer-reviewed, is funded by CAPT. Articles supporting the MBTI's validity in prominent scholarly journals are scarce, although Robert and Mary Capraro published a largely positive meta-analysis of its reliability in 2002 in *Educational and Psychological Measurement*.

Nonverbal Personality Questionnaire (NPQ)

Michael Patrick Mann

Mississippi College

The Nonverbal Personality Questionnaire (NPQ) is a structured nonverbal assessment of personality. The NPQ measures 16 different personality traits: achievement, affiliation, aggression, autonomy, dominance, endurance, exhibition, thrill seeking, impulsivity, nurturance, order, play, sentience, social recognition, succorance, and understanding. The 136 items on the instrument are made up of simple line drawings rather than written statements. Examinees are asked to consider each illustration depicting a personality relevant behavior and then rate the likelihood they would engage in that behavior on a 7-point Likert scale. The primary advantage of the NPQ is that it can be utilized with individuals who have reading impairments or language barriers. In addition, because of the nonverbal nature of the assessment, the NPQ can be useful for cross-cultural research.

The construction of the NPQ grew out of a controversy surrounding the assessment of personality. The controversy involved the claim that descriptors typically used to measure personality in assessments do not represent true components of personality. These descriptors merely represent words people commonly use to describe themselves and others. The evidence supporting this belief is that the underlying factor structures of most self and peer personality assessments are based on the semantic properties of the words used to measure personality in the assessments. The aim of the authors of the NPQ Sampo V. Paunonen and Douglas N. Jackson was to develop a structured nonverbal measure of personality. Other popular nonverbal assessments of personality including the Rorschach inkblot test and the Thematic Apperception Test are unstructured in their response format. This means the examinee can give an open ended verbal response to the presented visual stimuli of the tests. In this regard, the NPQ would be different from those measures. To develop their assessment, the authors first formulated verbal items representing specific behaviors based on the scales and items on Jackson's (1984) Personality Research Form (PRF). These scales on the PRF are based on Henry A. Murray's (1938) system of needs. These situational behaviors were then communicated to an artist who attempted to convey them pictorially. Three PRF content scales (Change, Cognitive Structures, and Defendence) were eliminated because the authors believed these represent cognitive behaviors and not observable

behaviors. The negative end of the Harm avoidance Scale of the PRF was utilized to create a new scale called Thrill Seeking. In addition, an Infrequency Scale using rare and undesirable items was created to detect random responding. A 202 unedited item pool resulted corresponding with 17 content scales from the PRF and one Infrequency Scale. Using psychometric data from various samples, the 202 item pool was eventually narrowed down to 136 items. These selected items represented the most psychometrically robust items. Later, the authors eliminated one scale (Abasement) due to poor scale and item properties. In its final form, the resulting scales of the NPQ include achievement, affiliation, aggression, autonomy, dominance, endurance, exhibition, thrill seeking, impulsivity, nurturance, order, play, sentience, social recognition, succorance, understanding, and infrequency. The authors believe there are a number of advantages to using a nonverbal measure of personality. Such an assessment could be used with nonnative language speakers, individuals who are dyslexic, and illiterate examinees. (For these examinees, the test administrator would give the instructions of the NPQ orally.) Also, the NPQ could be used to assess people with various speech pathologies. In addition, young children might find the drawings more attractive than an assessment with only verbal content. Mentally disordered clients with short attention spans could be properly assessed as well. Finally, because of the nonverbal content, the NPQ could be used in cross-cultural research studies.

A large international sample was utilized for the standardized process with data sets coming from Canada, England, Norway, the Netherlands, Germany, Poland, Israel, Russia, and Hong Kong. Internal consistency estimates ranged from .60 to .84 for each personality scale. In terms of convergence validity, for those in the standardization sample who completed both the NPQ and the PRF a moderate convergence was observed (M correlation = .46). For its underlying factor structure, 83.8% of the personality scales variance can be accounted by five meta-factors that correspond with the Five Factor Model.

Some reviewers of the NPQ have articulated a number of criticisms of the assessment in its present form. One concern involves the simple line drawings utilized in the items of the NPQ. Some of the items may be seen as ambiguous by examinees and lead to poor item reliability. Hence, more sophisticated artwork is warranted. Another concern is that a larger, more demographically representative sample than the one used to validate the instrument is needed. This would strengthen the evidence for the reliability and validity of the assessment. A final issue proposed by reviewers is that a greater understanding of the underlying structure of the NPQ is required. This, too, would strengthen its validation. The authors of the NPQ do state that the assessment is not "culture free." They and the reviewers suggest that the NPQ may be more relevant to Western, educated, middle-class individuals.

Objective-Analytic Test Battery (OA TB)

Wilfred Santiago, III[1] and Amanda ElBassiouny[2]

[1] *Spring Hill College*
[2] *California Lutheran University*

Creation of the Objective-Analytic Test Battery

The assessment of personality began as a collective effort by many psychologists, but Raymond Bernard Cattell was credited with creating a new approach to measuring personality that did not solely utilize self-report measures. This assessment was called the Objective-Analytic Test Battery. Cattell made three important observations in understanding personality that aided in developing the Objective-Analytic Test Battery. They were called Life Record, questionnaire, and objective tests. Respectively, they are known as L-Data, Q-Data, and T-Data. Initially, Cattell's research developed from the L-Data to determine what were the basic aspects of behaviors, which he named "Personality Sphere." The L-Data can be defined as a behavioral rating material because its measures are based on variables tested in a natural setting. Through his work, Cattell was able to use the L-Data factors that were yielded to create a hypothesis for the systematic extension of personality research in to Q-Data and T-Data. Q-data is defined as a questionnaire because a person self-reports personal qualities verbally. T-data is one of the main measures of the Objective-Analytic Test Battery. It can be defined as any test in which what is being measured reveals the same results regardless of who is administering it (Cattell, 1956). Cattell developed his 16 Personality Questionnaire, which was based more on Q-Data. He knew that there were some situations in which self-reports were necessary, but they have their limitations. When it comes to situations in which a participant can skew results through self-reporting by providing a socially desirable response or distorting the truth, objective tests are ideal.

The Objective-Analytic Test Battery

The underlying principle that the Objective-Analytic Test Battery was developed from is that personality is expressed in our actions. Who we really are is not what we say, but rather, what we do. Therefore, each Objective-Analytic Test is crafted in a way that the

results are not influenced by any other variable other than personality. The objectiveness of these tests leads advocates of Objective-Analytic Tests to think that it is a superior way of assessing personality. Both L-Data and Q-Data are susceptible to both voluntary and involuntary biases from the participant, due to the way in which they assess personality. However, T-Data avoids intentional deception since participants are not aware of what is being measured from the assessment (Santacreu, Rubio, & Hernández, 2006). Therefore, instead of measuring directly what a participant reports or only observing them in a natural setting, Objective-Analytic Tests measure behavior in such a way that the participant is unaware that personality is being assessed. Objective-Analytic Tests have been developed in a variety of formats, that includes 12 categories: performance tests, perceptual tests, ability tests, questionnaires, aesthetic tests, projective tests, opinionanaires, situational tests, games, physiological tests, incidental observation, and physical tests (Verma & Singh, 2014).

How Does it Work?

The Objective-Analytic Tests aim to keep elements of the test completely objective. The key difference here is that the individual that is being assessed does not know how that test is being scored. These tests are made to be an alternative to subjective self-report personality questionnaires and rating scales. Some projective tests, like the Rorschach inkblot test and Murray's thematic apperception test, do attempt to measure a person's personality without asking them directly (Schuerger, 2008). This is similar to Objective-Analytic Tests, but these tests are not direct enough. In one form of the Objective-Analytic Tests, participants are placed in miniature situations and their responses and reactions are recorded and measured. An example of this type of study is one that requires individuals to complete a half drawn image. Here, the participants are given the task to complete, but are unaware of how it will be scored or what precisely it is measuring. The researcher can score it by looking at the number of attempts it took to complete the image or examining the quality of the completed image. Additionally, Objective-Analytic Tests can also be structured in questionnaire format. In this form of Objective-Analytic Tests, participants may have to subjectively choose how they feel about a particular event, like levels of rewards for acts of heroism in the news. Though this choice is subjective on the participant's end, the objectivity with which it is scored is what qualifies it as an Objective-Analytic Test.

Types of Objective-Analytic Tests

There is a vast variety of types of Objective-Analytic Tests that comprise the battery. In total, psychologists can choose from about 500 Objective-Analytic Tests that can assess personality and ultimately predict behavior. One example of an Objective-Analytic Test that measures personality is the Picture Inspection Test. This assessment tests for emotional disturbance effects, like a person's aggression versus non-aggression through the use of pictures. Another example of an Objective-Analytic Test is the Tapping: Interrupted versus Uninterrupted Performance Test, which assesses for the honesty level of the participant

in a scenario-type situation. Although these tests are different in what they are testing, it is important to remember that these tests are objective and all belong to the same battery (Verma & Singh, 2014). A psychologist will pick a selection of these Objective-Analytic Tests, depending on what aspect of personality and behavior they are investigating.

Limitations and Strengths

The Objective-Analytic Tests, individually, have limitations. Each test measures a dimension of personality or behavior in such a specific way that it can be hard to generalize these results to other situations. The battery, however, is composed of so many of these tests that psychologists can choose multiple tests when testing a participant that can help with the issues of external validity. Thus, by utilizing more tests from the battery to increase external validity, there are many uses for these tests, such as assessing an individual's leadership qualities, organizational skills, and pro-social behaviors. They have recently been used to help with selecting and training military personnel. Consequently, Objective-Analytic Tests can be used to determine the general competence of army personnel and personality traits that are highly associated with success in that line of work (Verma & Singh, 2014).

Personality Assessment Inventory (PAI)

Jason M. Murphy

Southern Illinois University Edwardsville

The Personality Assessment Inventory (PAI; Morey, 1991, 2007) is an objective broadband self-report measure of adult personality and psychopathology with clinical, forensic, and personnel selection applications. The instrument is appropriate for individuals 18 years of age or older with at least a 4th-grade reading level. Administration requires approximately 50 minutes, with an additional 20 minutes for scoring. A Spanish edition of the PAI is also available. The 22-item Personality Assessment Screener (PAS) can be used to approximate the likelihood of important clinical elevations occurring on the PAI. For younger patients, the Personality Assessment Inventory – Adolescent (PAI-A), a 264-item instrument, can be administered to adolescents 12 to 18 years of age.

The PAI is composed of 344 four-point scale items constituting 22 non-overlapping scales: four validity scales (Inconsistency, Infrequency, Positive Impression, Negative Impression), 11 clinical scales (Somatic Concerns, Anxiety, Anxiety Related Disorders, Depression, Mania, Paranoia, Schizophrenia, Borderline Features, Antisocial Features, Alcohol Problems, Drug Problems), five treatment consideration scales (Aggression, Suicidal Ideation, Nonsupport, Stress, Treatment Rejection), and two interpersonal scales (Dominance, Warmth). The validity scales assess the potential influence of certain response tendencies, including random responding, systematic profile distortion, and positive and negative impression management. The clinical scales measure psychopathological traits judged to be relevant based on their historical and contemporary popularity among psychologists. Nine of the 11 clinical scales have subscales that represent more specific aspects of the trait. The treatment consideration scales provide indicators of potential treatment complications, assessing an individual's potential for harm to self or others, environmental circumstances, and motivation for treatment. The interpersonal scales assess interpersonal style along two dimensions: warm and engaging versus cold and rejecting, and dominant versus submissive.

Construction and Psychometric Properties

PAI development was based on a construct validation framework emphasizing both theoretical/rational and quantitative methods of scale development. This approach – choosing items based on both theoretical and statistical grounds – is unique to the PAI among well-known objective multiscale personality inventories, including the Minnesota Multiphasic Personality Inventory-2 and Millon Clinical Multiaxial Inventory-IV. PAI construction is also unique because its subscales do not share any items (Wise, Streiner, & Walfish, 2010).

Norms for the PAI manual were developed from three separate samples, each composed of over 1,000 participants: a census-matched general population sample, a college sample, and a clinical sample. A sound body of research supports the PAI's validity. Concurrent validity and diagnostic utility for the instrument's scales and subscales have been demonstrated across numerous studies. For instance, diagnostic applications are reported for college students, inmates, psychiatric outpatients, psychiatric inpatients, and medical patients. The convergent and discriminant validity of PAI scales relative to other self-report tests and clinician-rated measures have also been established. Construct validation using life-event data from forensic and substance abuse samples is also reported (Slavin-Mulford et al., 2012).

Internal consistency and test-retest reliability for the PAI are similarly well-supported. Internal consistency alphas for PAI full scales in general population, college, and clinical samples were each greater than .80 (excluding the Inconsistency and Infrequency scales, whose lower alphas are appropriate because they measure carelessness, not theoretical constructs). Test-retest reliability has been demonstrated in a sample of community members with administrations separated by an average of 24 days. All scales, again with the exception of Inconsistency and Infrequency, demonstrated test-retest *r*s greater than .75. Most scale *T*-scores changed only two to three points between the first and second administrations (Wise, Streiner, & Walfish, 2010).

Applications and Use

Clinical

The PAI full scales and subscales have diagnostic utility in both inpatient and outpatient clinical settings. For example, the Schizophrenia scale differentiates schizophrenic-spectrum diagnoses from inpatients with other diagnoses, the Borderline Features scale and its subscales identify individuals with borderline personality disorder among psychiatric outpatients, and differential diagnosis among college students with post-traumatic stress disorder (PTSD), depressive disorders, or social phobia has been demonstrated. Eleven PAI scales have been shown to identify significant life events, including suicide attempt, psychiatric hospitalization, trauma, medical problems, hallucinations, paranoid ideation, drug abuse, alcohol abuse, and arrest (Slavin-Mulford et al., 2012).

Forensic

The PAI is frequently used in forensic settings to predict different types of misbehavior, including institutional misconduct, violence, and recidivism. Specifically, scores on the Antisocial Features, Aggression, and Borderline Features scales have been identified as small to moderate predictors of misconduct in forensic treatment settings, with larger effects noted for correctional settings. Antisocial Features and Aggression have proven consistent and robust predictors of all types of institutional disciplinary infractions, criminal recidivism, and violence (Gardner et al., 2015).

The PAI is also useful in predicting the mental health needs of inmates. Its relatively low 4th-grade reading level is consistent with the low educational attainment of many prisoners. However, it still adequately identifies relevant clinical factors of interest to prison officials tasked with managing the behavioral and mental health needs of inmates. Treatment consideration and interpersonal scale scores aid predictions of treatment compliance and treatment interfering behaviors. Finally, the PAI addresses concerns of prisoners' self-report accuracy via the four validity scales incorporated into the instrument.

The PAI's use in the detection of malingering in forensic populations is also established. For example, feigned broad-range cognitive, somatic, and emotional symptoms associated with traumatic brain injury (TBI), as well as simulated posttraumatic stress disorder symptoms, are generally well-detected. Notably, but perhaps less relevant to forensic populations, research has demonstrated difficulty in detecting feigned attention deficit hyperactivity disorder using the PAI.

Personnel Selection

The PAI can be incorporated into evaluation procedures used to determine suitability for employment, particularly for positions that require considerable responsibility or pose significant on-the-job stress. Selection procedures for correctional officer and police officer roles have received significant research attention, yielding support for the PAI's use in evaluating applicants' appropriateness for these positions. In fact, the PAI offers a Law Enforcement, Corrections, and Public Safety Selection Report designed to assist in screening police and corrections officers, firefighters, emergency medical technicians, and communications dispatchers. In addition to the PAI's general population sample, a sample of more than 17,000 public safety applicants from various agencies across the United States is also available for use in scoring and interpreting applicants' protocols.

Strengths and Limitations

In addition to its clinical, forensic, and personnel applications, general strengths of the PAI include its low reading level, multiple large sample norms, readily understood constructs, and quick scoring. The instrument's 4th-grade reading level is accomplished through brief, straightforward item wording unlikely to confuse or inadvertently skew participants'

responses. In addition to the normative data from three large-scale samples included in the PAI manual, other sizeable norms, such as for public safety applicants, are available. Constructs measured by PAI scales are named with terms commonly used by psychologists and that can be readily understood. Two-part carbonless PAI answer sheets facilitate quick scoring without need for a separate answer key. Interpretive software is also available.

Limitations of the PAI include the absence of measurement of some constructs that may be of clinical interest and its use with individuals not fluent in English or Spanish. While the presence of eating disorders, such as anorexia and bulimia nervosa, may be indirectly intuited from the PAI's extant metrics, a direct measure of this construct is absent from the instrument's clinical scales. As with any psychological instrument, the PAI is intended for administration to individuals fluent in the language of its creation (i.e. English). While a Spanish edition of the PAI is available, interpretation of administrations to individuals not fluent in English or Spanish may yield invalid results.

Future Directions

Recent research suggests the PAI's utility in identifying military service members' level of impairment following TBI. With its multifaceted assessment of personality and psychopathology, examination of the instrument's ability to distinguish between the non-specific symptoms of TBI and PTSD seems likely. In addition to continued exploration of the PAI's utility for differential diagnosis in clinical populations, research on the instrument's forensic applications will also persist. Adding to the extant literature examining the PAI's predictive validity for male inmates, greater attention will be paid to its use with female prisoners. Continued evaluation of the PAI's ability to detect feigned psychological symptoms or disorders also seems likely. While sizeable PAI norms are available for use in law enforcement personnel selection, the opportunity exists to develop similarly robust data sets for evaluation of non-law enforcement aspirants, specifically applicants seeking non-law enforcement roles at the level of individual contributor, manager, or executive.

Revised NEO Personality Inventory (NEO-PI-R)

Dong Xie and Cory L. Cobb

University of Central Arkansas

The Revised NEO Personality Inventory (NEO-PI-R), developed by Paul Costa Jr. and Robert McCrae, was published by Psychological Assessment Resources, Inc. in 1992 and is one of the most widely used self-report inventories in personality assessment. It was originally developed by Paul Costa Jr. and Robert McCrae in 1985 as the NEO Inventory, the first instrument designed to specifically and systematically measure the five personality factors in the Five Factor model (FFM).

Five Factor Model (FFM): Theoretical Framework of NEO-PI-R

Overview of FFM

The FFM is one of many trait models in personality psychology that has received the most attention in the past four decades and is perhaps the most widely accepted model of personality traits theory. It focuses on the taxonomy of personality traits comprising five dimensions or factors that scholars of personality research have agreed to label as Neuroticism (N), Extraversion (E), Openness (O), Agreeableness (A), and Conscientiousness (C). The Five Factor model is also known as the Big Five theory. The term "Big" implies that these factors are broad and each of them describes a large number of more specific traits on a continuum that characterizes individuals whose traits vary from high to low on the factor. Scholars have generally agreed in regards to the meaning and description of these factors.

Specifically, in contrast to emotional stability, neuroticism summarizes various negative emotions such as anger, hostility, anxiety, depression, irritability, and insecurity. Individuals high in neuroticism are prone to stress, impulsiveness, and low tolerance for frustration. Extraversion and agreeableness concern interpersonal orientation. Extraversion subsumes traits such as being sociable, active, talkative, person-oriented, optimistic, need for stimulation, and capacity for joy; extraversion is in contrast to being reserved,

sober, independent, and quiet. Agreeableness describes traits of being soft-hearted and good-natured, trusting, compassionate, helpful, forgiving, and altruistic; agreeableness is in contrast to being cynical, suspicious, uncooperative, and ruthless. Openness, alternatively labeled as Openness to Experience, concerns the breadth, depth, and complexity of an individual's experience. People high in openness are curious, having broad interests, proactively seeking and appreciating various experiences; openness is in contrast to closed individuals who are conventional, conservative, dogmatic, and rigid in beliefs and attitudes. Conscientiousness describes traits in regard to degree of organization and persistence in goal-oriented behavior. People who are high in conscientiousness are organized, reliable, hard-working, self-disciplined, and persevering; conscientiousness is in contrast to those who are aimless, unreliable, careless, negligent, and hedonistic.

History of FFM

The FFM was developed based on a combination of lexical and empirical approaches. Researchers with a lexical approach believe that personality traits are important in daily life and therefore the languages used to communicate in daily life must contain words describing these traits. The origin of all personality trait models can be traced back to Gordon Allport and Henry Odbert's work in the 1930s when they identified, named, and classified personality traits through searching dictionaries to construct large pools of trait adjectives. Then James Cattell, with an empirical approach, factor-analyzed these traits by statistically sorting them into groups of related traits that are relatively independent of traits in other groups, which led to the development of his own framework of categorizing personality traits into 16 factors. During the late 1950s and early 1960s, two Air Force psychologists, Ernest Tupes and Ray Christal, reanalyzed Cattell's data and for the first time clearly claimed that the five factors were necessary and sufficient in summarizing human personality traits. However, their work remained largely dormant for the next two decades till the early 1980s when the lexical approach was resurrected. The FFM became more recognized and has been the dominant trait model guiding personality psychology since the 1980s, primarily due to Paul Costa Jr. and Robert McCrae's work of reanalyzing the archival data and the development of a series of instruments measuring these factors and their specific facet traits.

Research on FFM

The availability of NEO-PI-R, as well as its preceding versions, has enabled great advancement in personality psychology through numerous studies examining these factors and facet traits. For more than 30 decades, empirical research has accumulated to support the FFM. The five factors have been replicated in many studies using different samples, languages, and item formats. These dimensions have been demonstrated to have a high level of cross-cultural consistency in that they have been observed in more than 50 diverse nations across Eastern and Western cultures. The validity of this model

has also been supported by studies in identifying the emotional and behavioral correlates of these factors. For example, studies found extraversion, agreeableness, and conscientiousness to be associated with emotional well-being, social support, effective coping with stress, and experience of positive life events. On the other hand, neuroticism has been found to correlate with emotional distress, substance abuse, and self-blame. Research also demonstrated developmental stability of these traits and that some of these factors have a heredity component. Overall, research tends to suggest that the five factors may represent a universal structure of personality that transcends cultural differences.

Critics and Future Directions of FFM

However, in spite of the replicability of the five factor structure, there is still some disagreement regarding the content and replicability of the openness factor. Different researchers have used alternative names for openness, such as culture, intellect, and tender-mindedness. This might be due to the use of different materials (e.g. adjectives, questionnaire items) in different studies, or different interpretation of the meaning of "openness" across various cultural contexts; it may focus more on intellect in one culture, conventionality in the other, and openness in yet another culture.

Another question concerning the FFM is whether this model is comprehensive in description of personality traits. In spite of the accumulated evidence in support of its comprehensiveness, there has been increasing effort in identifying other factors beyond the five factors. Some research suggested that the FFM may not represent factors indigenous to certain cultures. For example, a sixth factor, named "Interpersonal Relatedness," was found in the personality structure of Chinese participants. Even though the openness domain was identified in the Chinese personality structure, the sixth factor Interpersonal Relatedness could not be explained by a combination of the five factors in FFM. This may suggest that a six-factor model might be better than the five-factor model for Chinese culture. Moreover, research has found cross-cultural differences with respect to the mean levels of these factors and traits, such that Japanese individuals score higher on neuroticism than Americans. Even though culture may not influence the structure of these factors and traits, the question remains open whether culture influences the mean level of these factors and traits.

A third criticism on FFM has focused on its failure to capture the underlying personality processes, though proponents of FM argued for this model as a framework for describing the phenotypic attributes of personality, rather than the mechanism in the development of these factors.

Apparently, research on the relevance, meanings, implications, and comprehensiveness of the FFM in cross-cultural contexts will continue to be a focus in the literature of this area. Research is also needed to relate the FFM personality structure to the underlying processes with respect to how biological, psychological, and social and cultural variables may impact the formation of the FFM personality structure. Acculturation studies will help to answer the question regarding if, and how, culture or ethnicity may influence the experience of these factors.

Development of NEO Inventories

Even though other instruments exist to measure the five factors, NEO inventories remain the most frequently used series of assessment for FFM. NEO-PI-R is the most recent version of a series of NEO inventories developed over the last several decades. Development of the NEO inventories can be dated back to Paul Costa Jr. and Robert McCrae's analysis of the archival data from a longitudinal study on male veterans collected in 1960s and data from their own study in the 1970s, both of which used earlier editions of the Sixteen Personality Factors Questionnaire (16 PF). These analyses identified three clusters from the 16 PF scales, neuroticism, extraversion, and openness to experience, and found that these three dimensions were very stable across time and different age groups. Specifically focusing on the openness to experience domain, Costa Jr. and McCrae developed the Experience Inventory by adapting some facets from an earlier, similar instrument, and by adding more scales to measure the specific facets of openness. They further hypothesized that personality domains consisted of sets of trait indicators, or subsets, and that an ideal personality instrument would measure the domain through a group of facets that were "mutually exclusive and jointly exhaustive of the domain."

This conceptualization of personality domains and instruments that measure these domains led to the development of NEO Inventory, an instrument with a total of 144 items to measure neuroticism, extraversion, and openness to experience, each of which consisted of six facets. Item factor analyses were used to select these items that loaded on both the general domain and the intended facet. A 5-point Likert-type response format was used. NEO Inventory can be administered through self-report (Form S) or through observer rating (Form R). Subsequent research using NEO Inventory provided evidence of its validity in that the hypothesized three-factor structure could be identified in both the self-report data and spouse rating data, as well as in the joint analysis of self-reports and spouse ratings.

However, the three-factor model in the NEO Inventory was soon found to be incomplete. Thus, the research team added two more domains, agreeableness and conscientiousness, along with an additional 18 items, leading to the publication of NEO Personality Inventory (NEO-PI) in 1985. NEO-PI was then slightly revised for use with college students and college-age norms were added. In addition, NEO Five Factor Inventory (NEO-FFI), a 60-item short version of the NEO-PI, was also introduced as a measure of the five factors only, without reports of the scores on their specific facets.

It should be noted that agreeableness and conscientiousness domains were added to NEO Inventory as global scales without the specific facet scales for each of the domains. Therefore, more items were developed and added to NEO-PI to create facet scales of agreeableness and conscientiousness domains in the same manner as the other three factors. This resulted in 12 new facet scales, six for each domain of agreeableness and conscientiousness, which led to the publication of Revised Personality Inventory (NEO-PI-R) in 1992.

Contents and Structure of NEO-PI-R

NEO-PI-R measures the five personality domains in FFM. Each of these domains consists of six facet scales with each facet scale containing eight items, resulting in a total of 30 facet scales and 240 items. These items are rated on a 5-point Likert-type scale including *Strongly*

Disagree (*SD*), *Disagree* (*D*), *Neutral* (*N*), *Agree* (*A*), to *Strongly Agree* (*SA*). These facet scales and items are balanced to control for acquiescence effect.

The five domains and 30 facet scales are summarized below with a brief description based on the Manual of the NEO-PI-R.

N: Neuroticism	Tendency to experience of psychological distress
N1: Anxiety	Experience of free-floating anxiety
N2: Angry Hostility	Experience of anger and related states
N3: Depression	Feelings of guilt, sadness, despondency, and loneliness
N4: Self-Consciousness	Shyness or social anxiety
N5: Impulsiveness	Act on cravings and urges rather than reining them in
N6: Vulnerability	General susceptibility to stress
E: Extraversion	Quantity and intensity of energy directed outwards
E1: Warmth	Interest in and friendliness towards others
E2: Gregariousness	Preference for the company of others
E3: Assertiveness	Social ascendancy and forcefulness of expression
E4: Activity	Pace of living
E5: Excitement Seeking	Need for environmental stimulation
E6: Positive Emotions	Tendency to experience positive emotions
O: Openness	Active seeking and appreciation of experiences
O1: Fantasy	Receptivity to the inner world of imagination
O2: Aesthetics	Appreciation of art and beauty
O3: Feelings	Openness to inner feelings and emotions
O4: Actions	Openness to new experiences on a practical level
O5: Ideas	Intellectual curiosity
O6: Values	Readiness to reexamine own values and those of authority figures
A: Agreeableness	Interactions one prefers from compassion to tough mindedness
A1: Trust	Belief in the sincerity and good intentions of others
A2: Straightforwardness	Frankness in expression
A3: Altruism	Active concern for the welfare of others
A4: Compliance	Response to interpersonal conflict
A5: Modesty	Tendency to play down own achievements and be humble
A6: Tender-Mindedness	Attitude of sympathy for others
C: Conscientiousness	Organized, persistent, and motivated in goal directed behavior
C1: Competence	Belief in own self-efficacy
C2: Order	Personal organization
C3: Dutifulness	Emphasis on fulfilling moral and ethical obligations
C4: Achievement Striving	Need for personal achievement and sense of direction
C5: Self-Discipline	Capacity to get job done on time
C6: Deliberation	Tendency to think things through before acting or speaking

Forms of NEO-PI-R

Other forms of NEO-PI-R exist for different purposes and populations. NEO Five Factor Inventory (NEO-FFI) is a short form of NEO-PI-R. It has 60 items that measure the five factors only and does not contain the items used to assess the facet traits within each domain. The NEO-FFI is appropriate to use in situations where there is not enough time to respond to all items on the NEO-PI-R and when scores on facet scales are not necessary.

NEO-PI-3 is the adolescent version of NEO-PI-R and was developed for adolescents 12–17 years of age. Items in the NEO-PI-R were revised or edited to lower the required reading level and make the instrument more appropriate for younger examinees or adults with limited literacy. As a result, items in NEO-PI-3 are easier to read and understand than those on the NEO-PI-R. Research is being conducted to determine whether the NEO-PI-3 can replace NEO-PI-R for use with individuals at all ages.

The most recent form of NEO-PI-R is the NEO Personality Inventory-3: Four-Factor Version (NEO-PI-3:4FV) that is designed for use in personnel selection, employee training, and career counseling and career development settings. The NEO-PI-3:4FV focuses on four personality domains: Extraversion, Openness to Experience, Agreeableness, and Conscientiousness. Items, norms, and scoring of these four domains are taken from the same domains of the NEO-PI-3.

All of these NEO inventories have two forms in terms of administration: Form S (Self) and Form R (Rater). Form S is administered to be completed through self-report by the individual being evaluated. Items in Form R are written in the third-person for peer, spouse, or expert ratings. Form R is to be completed by someone who is knowledgeable of or well acquainted with the individual being evaluated. While Form S is administrated on most occasions, the use of Form R in conjunction with Form S may provide additional information. For example, in couples' counseling, using both the Form S and Form R of NEO-PI-R may help the couple to better understand the discrepancy between their perceptions of each other and the counselor to better conceptualize their relational problems and improve their communication.

Administration, Protocol Validity, and Scoring

Administration

NEO-PI-R is for administration to adults 18 years or older with at least a 6th-grade reading level. It can be administered in the paper-pencil format, or by computer, or by playing cassette tapes. Administration of NEO-PI-R may take 20–30 minutes. The person who administers NEO-PI-R is expected to have adequate knowledge regarding psychological assessment in general and NEO-PI-R in particular for his or her qualifications to administer the instrument.

The administration of NEO-PI-R should take place in a cozy and quiet environment without external distraction. The examiner should begin by building rapport with and gaining full cooperation from the individual to be evaluated. The examiner should ask whether the examinee has any questions regarding the instrument or concerns about the

evaluation process. The examiner should also answer relevant questions, explain the nature and purpose of the assessment, and give feedback on the assessment if needed. Although the examinee is expected to have a reading level of 6th grade or above, the examiner can read the items to those who have limited reading abilities. The NEO-PI-R is one of the very few self-report personality inventories that allow the examiner to read the items to examinees, which is strongly discouraged or forbidden in most other self-report inventories.

Checking Protocol Validity

It is necessary to check the protocol validity of NEO-PI-R before scoring. Unlike many other multi-dimensional self-report personality inventories such as Minnesota Multiphasic Personality Inventory-2 (MMPI-2), the NEO-PI-R does not have built-in validity scales to detect possible response distortions (e.g. faking good or faking bad tendencies) and response inconsistencies. However, protocol validity can be assessed by examining the number of omitted items and the three validity check items at the bottom of the answer sheet. Scoring of the NEO-PI-R answer sheet should not proceed if more than 40 items have been omitted. Individual facet scales should not be scored if more than three items on that facet scale have been omitted.

The three items at the bottom of the answer sheet serve as validity checks. These questions ask if the examinee has answered all of the questions honestly and accurately, responded to all of the statements, and entered the responses in the correct area. Responses of *Disagree* or *Strongly Disagree* to the first validity check and *No* to the last validity check suggest protocol invalidity. If administered through computer, the computer generated NEO-PI-R interpretive report will include a check for consecutive and repetitive endorsement of the same response options, such as six responses of *Strongly Disagree* in a row, nine responses of *Disagree* in a row, 10 responses of *Neutral* in a row, 14 responses of *Agree* in a row, and nine responses of *Strongly Agree* in a row. All of these also suggest invalidity due to random responding. Furthermore, the sum of the numbers of *Agree* (*A*) and *Strongly Agree* (*SA*) responses can be used as an indication of the acquiescence bias. If the examinee has responded with *A* and *SA* options to more than 150 items, or responded with *A* and *SA* to less than 50 items, then acquiescence bias or naysaying bias may exist, and the NEO-PI-R should be interpreted more cautiously than when the five response options are more evenly distributed across the items. Another option to check the protocol validity of NEO-PI-R is to calculate the cross-observer validity coefficient, which involves use of both the Form S and Form R. The protocol validity can then be examined by the correlation between the responses on these two forms, one completed by the individual being evaluated and the other by his or her acquaintance.

It is recommended that the examiner scan the answer sheet for omitted items or double-marked items before the examinee leaves the evaluation. This is done so the examinee can be asked to complete the omitted items or make clarifications on the double-marked items. If responses to the three validity check items suggest protocol invalidity, reasons behind these responses should be explored and taken into account in further determining the protocol validity and interpreting the results. When invalid cases may be indicated in research settings, researchers are recommended to analyze the data separately, with the possible invalid cases included and excluded, and to compare these results. In clinical settings, clinicians

may still proceed with the interpretation but more cautiously. Use of Form R to obtain observer's ratings can be another option.

Scoring

Scoring of the NEO-PI-R is automatic if administered by computer. If the answer sheet is used to record examinee's responses, then their responses can be either entered into the computer program for scoring or hand scored. It is recommended to enter the responses twice into the computer for scoring to avoid data entry errors. The NEO-PI-R answer sheet provided by its publisher is a two-page carbonless answer sheet for self-scoring. However, before removing the top page, the examiner should first clear up the answer sheet by clearly marking the omitted or double-marked items so that these items will not be counted in scoring. Occasionally, the examinee may change their response on one item. When this happens, the examiner needs to clearly mark the response the examinee actually endorsed to ensure it will be counted in scoring. The second page of the answer sheet displays values associated with *SD*, *D*, *N*, *A*, or *SA* in rows and each row corresponds to one of the facet scales for each domain. The sum of the values associated with the marked responses yields the raw score for each facet scale and the sum of the raw scores of the six facets within a domain yields the raw score for that domain. The values assigned to *SD*, *D*, *N*, *A*, or *SA* are 0, 1, 2, 3, 4, or 4, 3, 2, 1, 0 when the item is keyed in reversed direction. There are eight items for each of the facet scales and therefore, the raw score range for each facet scale is 0–32 and the raw score range for a domain is 0–192.

Interpretation

General Guidelines and Cautions

A general guideline for interpretation of scores of a personality inventory is *never* to rely on the scores only. Instead, an examiner should always take into account all other information, such as protocol validity, reasons and purpose of assessment, examinee's motivation, observed emotional state, and behavior during assessment. This is particularly important for interpretation of NEO-PI-R because of its lack of validity scales to detect faking-good or faking-bad tendencies. Although not likely an issue in research settings when participants volunteer in the assessment and complete the inventory anonymously, response distortions are more likely to occur in settings that involve clinical, forensic, and personnel evaluations when individuals to be assessed may have a motivation to present themselves favorably or pathologically.

In spite of NEO-PI-R's significant usefulness in various settings reviewed in sections below, some cautions should be kept in mind while interpreting its results. First, the development of NEO-PI-R is based on research using normal adult samples and is intended to provide information on basic and general personality dimensions. In other words, NEO-PI-R is not a measure of psychopathology like the MMPI-2. Therefore, examiners who work in clinical settings should be cautious in making a highly pathological inference of a score. For example, a high score on Neuroticism should not by default be interpreted as psychopathology; rather, it may need to be viewed as a general dissatisfaction of life or a proneness to negative life affect.

Similarly, although high scores on some domains may seem to be more socially favorable and psychologically healthier, low scores on these domains do not necessarily suggest inadequacy and negativity. High or low scores on these domains should not be interpreted in a naïve manner as being positive or negative traits. For example, a low score on Extraversion should be viewed as an absence of extroversion traits rather than the opposite of extraversion that suggests a deficit or psychopathology. People with low scores on Extraversion should be considered reserved but not unfriendly. They may prefer to be alone but this does not mean they experience social anxiety. Also, although high scores on Openness suggest being open to various values, they do not necessarily imply these people are unprincipled or do not have their own values. It is important to keep in mind that the quality of these traits, either high or low, depends on the environment that an individual interacts with. People with high scores on the Agreeableness domain may find that being too agreeable is a challenge in situations where they must be independent and skeptical.

A third caution might be more applicable when interpretation of NEO-PI-R results is for comparison between two individuals. It is important to remember that two persons may have similar scores on a domain, but their scores on specific facet scales of the domain can be very different. Therefore, to obtain a comprehensive and accurate understanding of an individual based on his or her NEO-PI-R scores, it is important to examine both the domain scores and facet scores, particularly in clinical, educational, and career development settings.

General Interpretation Process

Once determined to be appropriate after assessing the protocol validity, interpretation of NEO-PI-R should begin with the scores on the five broad personality domains, following by scores on the specific facet scales within each of the domains. A T score is used to facilitate interpretation of NEO-PI-R. For both the domain scores and facet scale scores, a T score between 45 and 55 is regarded as *average*, whereas T scores below 45 are regarded as *low* and above 55 as *high*. T scores below 35 are regarded as *very low* and T scores above 65 as *very high*. The manual of NEO-PI-R provides descriptions of the personality traits for the domains and facets at these low and high levels. The raw scores can be plotted and transformed to T scores on normed profile sheets, which can then be interpreted in reference to NEO-PI-R manual as well as literature about the NEO-PI-R.

Computer-Generated Interpretive Report

As mentioned earlier, NEO-PI-R has the option of computer administration, scoring, and interpretation. The current NEO-PI-R software generates an interpretive report that includes the examinee's identifying information, a T-score profile displaying the examinee's standing on the five factors and 30 facet scales, and a table summarizing the raw scores and T scores in ranges of average, low, high, very low, or very high. The report also provides a global description of the five factors, followed by a detailed interpretation of the facets of these factors. Occasionally, interpretive statements at the factor level may be

inconsistent or even conflict with those at the facet level. In these situations, attention should be focused on the facet scales and their interpretations. Additionally, the report provides possible implications of the examinee's personality profile for their functions in coping and defense, somatic complaints, psychological well-being, cognitive processes, interpersonal characteristics, and needs and motives. However, it should be noted that these implications only give a sense of how this person may function in these areas and should *not* be viewed as direct measurements of these functions.

Lastly, the computer-generated interpretive report proposes clinical hypotheses regarding personality disorders and treatment implications based on the similarity of the examinee's profile to the prototypic profile of NEO -PI-R facets. These prototypic profiles are characterized with the facets that are consistent with the criteria of a personality disorder formulated in fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV*). However, it should be noted that information in this section of the interpretive report is intended for clinical populations only and should be interpreted in reference to other clinical information and evidence.

Again, consistent with the general guidelines described at the beginning of this section, information provided in this computer-generated NEO-PI-R report should be viewed as only one source of information and should be integrated with all other sources of information to reach professional decisions about the examinee. The report is intended for qualified professionals only and should not be released to the examinee.

Other NEO-PI-R Profiles

Many applications of NEO-PI-R require giving examinee feedback about their results on NEO-PI-R. In spite of the restrictiveness of releasing the standard interpretive report, NEO-PI-R has an option of generating a brief report named *Your NEO Summary* as a feedback sheet that can be released to examinees. This one-page brief report, in lay terms that are easy to understand, gives the examinee a general idea of his or her personality described along the five broad dimensions.

In addition to the above reports, other forms of NEO-PI-R profiles are available for the use of the NEO-PI-R in clinical settings, as well as settings of personal selection and career counseling and development. The NEO Job Profiler can be used to select employees by weighing a candidate's traits against the qualities needed for success in a given position. The *NEO Style Graph Booklet* presents graphs in an innovative way to show examinees how their particular personality domains interact with each other and form different areas of their personality. This booklet can be used in career planning and development. Apart from the personality disorder hypotheses and implications included in the standard interpretive report, the *NEO Problems in Living Checklist* offers additional information that can assist clinicians in planning treatment and assessing treatment progress.

Psychometric Properties

This section summarizes the psychometric properties of NEO-PI-R. Overall, these properties have been found to generalize across ages, cultures, and forms of measurement.

Reliability

For the five domains of NEO-PI-R, the internal consistency reliability coefficients for a college sample are 0.92 for both Neuroticism and Extraversion, 0.89 for both Openness and Agreeableness, and 0.93 for Conscientiousness. The manual reports similar internal consistency coefficients based on a non-college sample (n = 1,539), 0.92 for Neuroticism, 0.89 for Extraversion, 0.87 for Openness, 0.86 for Agreeableness, and 0.90 for Conscientiousness. The internal consistency coefficients for the facet scales ranged from 0.56 to 0.81 with Tender-Mindedness (A6) being the lowest (0.56) and Depression (N3) the highest (0.81). The test-retest reliability coefficients have been reported with different intervals. The NEO-PI-R manual reports test-retest reliability with a six-year interval as 0.83 for Neuroticism, 0.82 for Extraversion, 0.83 for Openness, 0.63 for Agreeableness, and 0.79 for Conscientiousness. One study reported test-retest reliabilities over a 10-year interval with a range of 0.78–0.85 for the five domains and 0.57–0.82 for facets scales. Another study on the short-term test-retest reliability over a one-week interval was 0.91–0.93 for the domains and 0.70–0.91 for facets scales.

Validity

With respect to validity of NEO-PI-R, the manual reports correlations between the NEO-PI-R domain and facets scores and scores obtained from other well-established personality assessments measuring similar constructs. The Introversion score measured by the Myers-Briggs Type Indicator (MBTI) has a correlation of −0.61 with the score of NEOPI-R's Warmth facet (E1), −0.59 with the Gregariousness facet (E2); MBTI's score on Intuition has a correlation of 0.43 with the NEO-PIR's Fantasy facet (O1) score and 0.56 with its Aesthetics facet (O2) score. In addition, NEO-PI-R's facets scores are correlated in the expected direction with some of the personality types measured by the Self-Directed Search (SDS), a commonly used personality assessment in career counseling and career development: 0.56 between the Aesthetic facet (O2) and SDS's Artistic type, 0.43 between Ideas facet (O5) and SDS's Investigative type, and 0.36 between Tender-Mindedness (A6) facet and SDS's Social type.

Consensual validity of NEO-PI-R has been supported by the strong correlation between self-report scores obtained through Form S and scores based on acquaintance's ratings using Form R. Criterion validity of NEO-PI-R has been established through identifying relationships of NEO-PI-R domain and facet scores with external criterion variables. For example, Conscientiousness was found to predict GPA of college students above and beyond SAT scores and significant relationships have been found between Neuroticism and emotional exhaustion, and between Agreeableness and personal accomplishment. Additional evidence for NEO-PI-R's criterion validity can be found in the review of similar findings in the next section.

Application of NEO-PI-R

NEO-PI-R in Research

NEO-PI-R, as well as other NEO inventories, has been widely used in research as well as in more applied settings such as clinical, educational, occupational, and industrial/organizational settings. One area of research in personality psychology involving

NEO-PI-R focuses on cross-sectional comparisons of the five-factor structure across different cultures, nations, gender, ages, and other demographic variables. NEO-PI-R has been translated into and validated for more than 40 languages and has been the most extensively used self-report instrument in cross-cultural studies. Overall, these findings support the universality of the five-factor structure across various cultures, nations, languages, ages, and gender. Therefore, NEO-PI-R, as a reliable and valid instrument for research, has made a significant contribution to the accumulation of empirical evidence for FFM and the consolidation of FFM as a leading model in personality research.

While the five-factor structure may be everywhere for everyone, there are gender and age differences with respect to levels on certain factors. Older adults are lower in Neuroticism, Extraversion, and Openness, and higher in Agreeableness and Conscientiousness than younger adults. Adult females are overall higher in all of the five factors than adult males. More importantly, this pattern of differences, though small, has been found to be very similar across different cultures and societies. This may have challenged some of the traditionally presumed hypotheses regarding the environmental, social, and cultural influences on the development of personality. In the field of personality psychology, it has generally been believed that personality is shaped a great deal by contextual factors such as historical experiences of different generations, parenting styles, socialization, and other early life experiences. However, if this is true, then different patterns of the age and gender differences would be observed across different cultures and societies. The consistent findings of age and gender differences on FFM factors across cultures suggest these differences might be more due to biological reasons, such as maturation, than contextual variables.

Another area of research focuses on the use of NEO-PI-R to identify factors or facet traits that may predict certain outcome variables, particularly in industrial/organization (I/O) psychology. Indeed, the personality trait model has facilitated significant advances in I/O psychology's inquiry of determinants of work outcomes. Thus, the NEO-PI-R has been most frequently used as an important tool to identify personality traits, at both the broad domain level and the specific facet level, which can predict job performance, occupational safety, leadership, management, and other vocational behaviors. Research has found all the five factors are highly relevant to many outcome variables in I/O psychology. Among them, Conscientiousness has been the primary focus of attention and has been identified as an important predictor of job performance for various types of occupations. Openness has been found to predict learning and training outcomes and job performance where adaption to change is required. Positive relationships have been identified between Extraversion and leadership as well as effective job interviews. Agreeableness predicts teamwork, quality of customer service, and interpersonal facilitation. Putting all of these findings together, Conscientiousness, Openness, Extraversion, and Agreeableness appear to be important factors predicting job satisfaction while Neuroticism predicts job dissatisfaction and occupational stress and burnout.

In the area of research on career development and career counseling, NEO-PI-R has been used to identify factors and facet traits that are associated with academic and occupational success in certain majors and occupations. For example, high score in Conscientiousness may indicate academic success in chemistry and accounting while

high score in Openness may indicate success in philosophy and literature. People with high scores on Extraversion and Agreeableness may be more satisfied and successful with occupations that involve a great deal of interpersonal interactions such as sales, teaching, and tutoring, rather than with occupations that require a lot of time being alone, where people with low scores on these domains may feel more comfortable and satisfied.

In recent years, increasing attention has been paid to NEO-PI-R for use in clinical research. With the NEO-PI-R, an increasing number of studies has found the clinical relevance of the FFM domains and their facet traits to psychopathology such as depression and personality disorders. One potential clinical application of NEO-PI-R is to provide information regarding diagnosis of personality disorders. The current fifth edition of *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-V*) proposes an alternative personality trait model for personality disorders that specifically focuses on personality functions and pathological personality traits. *DSM-V* defines personality functioning in terms of self (i.e. identity and self-direction) and interpersonal (i.e. empathy and intimacy) aspects. The pathological personality traits consist of five broad domains: Negative Affectivity (vs. Emotional Stability), Detachment (vs. Extraversion), Antagonism (vs. Agreeableness), Disinhibition (vs. Conscientiousness), and Psychoticism (vs. Lucidity). Indeed, these traits are nicely aligned to the maladaptive aspects of the five factors in FFM. These five pathological trait domains consist of subsets of 25 specific trait facets that are clinically relevant to personality disorders. Apparently, there has been a good fit between FFM and *DSM-V*'s alternative personality trait model of personality disorder. NEO-PI-R has been used as a major measurement in the majority of studies to identity the traits related to personality disorders. It also plays an important role in the operationalization of alternative trait model of personality disorder and will continue to be a useful tool in empirical research as well as in accurately diagnosing these personality disorders. Many of the most recent studies on FFM and personality disorders, as well as use of NEO-PI-R to evaluate the pathological traits, have been published in the third edition of *Personality Disorders and the Five-Factor Model of Personality*, edited by Thomas Widiger and Paul Costa, Jr., which was published by the American Psychological Association in 2013.

NEO-PI-R in Practice

Application of the NEO-PI-R in the above-mentioned research areas has yielded findings that not only support the predictive and criterion validity of the NEO-PI-R, but also have important implications for practice in their corresponding applied fields. Educationally, NEO-PI-R can be used in academic advising to help students understand their traits that may facilitate or impede their academic success with their selected majors. In career counseling, it can be used to help clients develop career choices that are congruent with their traits and help them make more effective career decisions. NEO-PI-R can also be used to help clients understand the strengths and challenges of their traits given the occupations of their interest. In industrial and organizational settings, NEO-PI-R can be used in personnel selection and human resource management.

Although NEO-PI-R has been increasingly used in clinical research, its potentiality in clinical practice has yet to be explored. The relative limited application of NEO-PI-R in clinical practice is in part due to its lack of validity scales to detect response distortions that might be more likely in clinical settings than non-clinical settings. Another reason is that the NEO-PI-R has been described as a measurement of normal personality and is often mistakenly limited to use with normal populations only. However, it is important to keep it in mind that NEO-PI-R is a measure of general personality which can be used with everyone, not only those with normal personalities, but also those with various forms of psychopathology.

NEO-PI-R can be used in clinical practice to facilitate understanding clients, making an accurate diagnosis, and providing appropriate interventions. Indeed, NEO-PI-R may have several advantages over other more frequently used assessment in clinical practice. First, the information NEO-PI-R provides is non-pathological which can balance the heavy focus on psychopathology in most of the assessment tools in clinical settings. Second, administration of the NEO-PI-R has a strong emphasis on building rapport with patients, which will facilitate treatments given that working alliance has been found to be a robust common factor for effective interventions regardless of their underlying theoretical orientations. Third, NEO-PI-R can provide information on the strengths of the patients that can be inferred from their traits. This information will facilitate the integration of treatment of the psychopathology with other strength-based interventions such as education and career counseling. Such integration is in line with the positive psychology movement in clinical settings. Lastly, use of Form R of NEO-PI-R, which can be completed by a family member, can facilitate the involvement of family members in treatment. The Form R might be particularly useful in couples' therapy because it can help to illustrate the discrepancies of their perceptions of each other's traits and facilitate effective communication between the two.

NEO-PI-R can also be a useful tool in integrated healthcare, a recent movement that promotes the integration of psychological services to healthcare in medical settings. This instrument can help to identify patients' personality traits that may have an impact on their medical conditions. High scores on Neuroticism may suggest a predisposition to distress and its possible impact on a patient's medical conditions. NEO-PI-R can help to identify a patient's personality traits that may facilitate or impede treatment of his or her medical conditions. For example, patients with high scores on Conscientiousness may be more likely to follow through the treatment, particularly those involving long-term and complex procedures.

Critiques of NEO-PI-R

Lack of built-in standard validity scales is probably the criticism that the NEO-PI-R has received the most and is probably the main reason for its limited application in clinical settings. One drawback that all self-report personality inventories share is the response distortion due to social desirability or malingering, which compromise the validity of these instruments. Therefore, many self-reported instruments have built-in validity scales to detect these distortions. For example, the MMPI-2 has several empirically developed

validity scales; the basic validity scales include the *L* (Lie) scale to detect self-favorable tendency, the *K* (Correction) scale to detect those whose psychopathology can be embedded in a normal profile, and the *F* (Infrequency) scale to detect self-unfavorable tendency. Analyzing the configurations of these validity scales can effectively detect response distortions such as faking good or faking bad. However, this is not the case for the NEO-PI-R, probably because this instrument was originally developed for use with normal populations for whom response distortion may not be a concern. Perhaps its potentiality for use with populations with psychopathology was not recognized when the original NEO inventory was developed. NEO-PI-R does have three validity check items, but they might be too obtrusive and individuals who intend to distort will be able to easily manipulate their responses to these items so the distortion will not be revealed. Therefore, without the assistance of standard validity scales, an examiner's decision on protocol validity is more likely subject to bias.

To address this limitation, researchers have developed some validity scales from NEO-PI-R's own item pool to assess common response distortions such as tendencies to present oneself in an overly positive or negative manner, and response inconsistency. These validity scales have been found to be effective at identifying participants instructed to present themselves positively or negatively. However, the validity and usefulness of these validity scales may depend on the specific purposes and populations for which the NEO-PI-R is being used. Studies suggested that, in research settings where a large number of participants are assessed, use of these validity scales to remove invalid protocols may not influence the results. However, in clinical settings, removal of invalid profiles based on these validity scales can increase the correlations between NEO-PI-R scores and the outcome variables that are presumably predicted by the scores. Apparently, validity issues in application of NEO-PI-R, particularly in clinical populations, will continue to be the focus of research.

Zuckerman-Kuhlman Personality Questionnaire (ZKPQ)

Alisha Conover

University of California, Irvine

Personality can only be assessed through questionnaires and measures because the traits are a personal reflection and are not exhibited through any physical change. Through years of research and growth there have been multiple developments in the personality questionnaires being used. While preparing to write his book *Psychobiology of Personality*, Marvin Zuckerman realized that biological and genetic bases of personality traits were not available and alongside his colleagues he set out to develop an alternative five factor model to measure personality or temperament. In identifying the five basic personality traits, Zuckerman looked to those with a strong biological-evolutionary basis. Zuckerman was able to identify these five innate factors by administering pre-existing personality questionnaires such as the Sensation Seeking Scale, Biological Basis of Personality, and Big Five to research participants on a large scale. The results of these questionnaires and personal reports were subjected to a classical factor analysis to identify the innate factors that are the core of an individual's personality. To develop what would later become the most widely used personality questionnaire, Zuckerman and his team selected 46 scales from eight random questionnaires to represent the hypothesized factors. To account for the probable hierarchical nature of the structure the results were tested on multiple factor levels. After careful sampling of the postulated traits on large samples, the factor analyses yielded a robust five-factor structure that offered maximum specificity and factor reliability in both male and female subjects.

The Development of the Five Factors

Zuckerman and his associates wanted to identify the biological factors of personality. When analyzing the data of other personality questionnaires used in psychobiological research, they looked for scales that could be found across human and non-human species.

The psychobiological based personality traits of the alternative five were identified, and those factors are now established in the Zuckerman-Kuhlman Personality Questionnaire (ZKPQ). The five constructs that are measured in the ZKPQ are Impulsive Sensation Seeking (ImpSS), Neuroticism-Anxiety (N-Anx), Aggression-Hostility (Agg-Host), Sociability (Sy), and Activity (Act) components. The entire questionnaire can be completed in about 20 minutes at most and consists of 99 true-false items. There is a 10 item validity scale to eliminate any individual reports that are influenced by extreme social desirability. The other 89 items represent each of the factors based on high correlations with the factor and lower correlations with other factors.

Impulsive Sensation Seeking

The Impulsive Sensation Seeking Scale (ImpSS) has 19 items and looks at risky and thrill-seeking behaviors as well as lack of planning and acting on impulse. This scale has been shown to have many biological correlates and was an original development of Zuckerman. Each of the 19 items is either impulse or sensation seeking driven and they measure the extent to which each person displays such qualities. The Impulsive Sensation Seeking Scale that was developed in the ZKPQ replaced specific activities, such as inappropriate speeding and other driving tactics that put oneself in physical and/or legal harm, with more generalized ones. Novelty and intensity of the activity are important but not the whole story. High-sensation seekers usually drive more recklessly than their low-sensation seeker counterparts. Zuckerman has worked on evolving the sensation seeking construct for over 50 years in order to eliminate confounding in studies where people might engage in one or another of these activities. The Sensation Seeking Scale looks to measure the following variables: Thrill and Adventure Seeking, Experience Seeking, Disinhibition, and Boredom Susceptibility. The Sensation Seeking Scale that Zuckerman has developed throughout the years remains one of the most widely used of the sensation seeking scales. The structure of the Western-based Sensation Seeking Scale has seen success in its replications and across multiple countries and cultures.

Neuroticism-Anxiety

The Neuroticism-Anxiety Scale (N-Anx) within the personality questionnaire has 19 items that ask you to explain how you feel, if you have trouble with various circumstances, and if you tend to react specifically to various interactions with others. These items ask the person to describe their level of emotional upset and tension such as whether you feel edgy and tense. Of the 19 items, a number of them also touch on worry, fearfulness, and obsessive indecision by asking whether the person has trouble making decisions. Lastly, the items question whether you tend to be sensitive or hurt by the thoughtless actions or comments of others in order to gauge a person's lack of self-confidence and sensitivity to criticism. It is through these items that Zuckerman is able to look at the fear and worry aspects of a person's personality.

Aggression-Hostility

The Aggression-Hostility Scale (Agg-Host) is 17 items and reflects on one's readiness to express aggressive and hostile verbalizations or behavior. This scale also seeks to discover whether a person has a quick temper or irregular impatience toward others. For verbal aggressions, one of the items asks whether cursing is a common verbal response when one is mad. Another item asks whether you feel the need to express how you feel toward people even if it is negative. Lastly, items focus on the person's temper asking if you cannot help but get into arguments when people disagree with you.

Sociability

The Sociability Scale (Sy) is 17 items. The items focus on two factors in order to measure a person's sociability. The first factor is a group of items that look at the liking of big parties and lots of friends. The second factor is measured through a group of items that indicate both an intolerance for social isolation in subjects that enjoy being social as well as a tolerance for isolation in subjects who feel comfortable being unsocial.

Activity

The Activity Scale (Act) is 17 items and looks at two factors as well, whether you feel restless when there is nothing to do and whether you have a preference for challenging and hard work. To measure these items questions are asked such as "I like to keep busy all the time" or "I like a challenging task more than a routine one."

Including the five measurable personality scales there are also 10 items that measure infrequency. These items are used to eliminate subjects with scores that may result in invalid records. These 10 items are most true scored and if they are endorsed they indicate exaggerated socially desirable content that is unlikely to be true. If the subject scores higher than a 3 than their validity is considered arguable.

Validity of the Five Factors

Furthermore, the internal reliability within all of the scales is good with most alphas of each scale ranging between .70 and .80. Of all the scales the highest reliabilities across all samples were found in the N-Anx measure with both males and females. The ZKPQ has shown to be reliable in what it claims for different areas such as drug abuse, sex, gambling, and sports. The five scales within the questionnaire revealed moderate to high correlations to ratings by family and friends. Compared to other popular personality measures, the ZKPQ was able to show good construct and discriminant validity in four of the five scales revealing a high reliability rating. So much so that the ZKPQ has been used to measure personality disorders among the general population. Over the development and issuing of the personality assessment, some areas of improvement began to surface and the re-development of the Zuckerman-Kuhlman Personality Questionnaire began.

The Development of the Zuckerman-Kuhlman-Aluja Personality Questionnaire

Research in the field of personality suggested that facets provide better predictive validity in determining behavior when compared to only looking at higher-order traits. While the ZKPQ was originally developed without facets it was revealed that two factors were found consistent within three of the original measures. The Impulsive Sensation Seeking Scale contained impulsivity and sensation seeking factors. The Sociability Scale did account mainly for sociability, but an intolerance of isolation factor was also present; and the Activity Scale included a need for general activity that encompassed impatience and restlessness and need for work activity including energy for work and life's other activities. The variation that was unveiled determined that the five factors were clearly not adequate to distinguish among facets within the traits. Another development that came with the new instrument of personality was the change from a true-false to a four-category, Likert-type response scale. There were two stages in the development of the new instrument; the first was to define the likely candidate facets that could be theoretically related to the original five ZKPQ factors and the second was to determine the consistency of the facets to the factors and vice versa. The new test was named the Zuckerman-Kuhlman-Aluja Personality Questionnaire (ZKA-PQ) to recognize the major role of A. Aluja and to acknowledge it as a new measure.

Directions for Future Research

While the development of the ZKPQ began in the 1980s, its effectiveness and popularity as a personality measure have remained monumental within the field. The Five Factor Model is one of the only personality measurements with a psychobiological basis and thus makes it a new development in the field. The easy availability of the ZKPQ allows interested researchers the opportunity to analyze personality through the instrument especially in fields with a strong biological background. Major developments of the ZKPQ in translated scales such as German, Spanish, Catalan, Japanese, and Chinese have shown impressive internal and factor reliability and further translations are also an area of continued growth for the scale. While the model is evolving, illustrated through the development of the ZKA-PQ, there is still much more research needed to develop the model to its fullest potential.

Projective Techniques, General Features and Methodological Issues

H. Russell Searight

Lake Superior State University

Projection, a classical Freudian defense mechanism, protects the ego from anxiety arising from unconscious intrapsychic conflicts. To maintain psychological safety, undesirable characteristics of one's own are attributed to others such as when an unfaithful husband accuses his spouse of having an affair. While being a normal ego function operating outside of conscious awareness, projection is a relatively immature defense. Developmentally, projection as a coping strategy follows denial and is active from age[6–8] until late adolescence.

Projection and Personality Assessment

While recognizing its unconscious status, personality researchers and clinicians view projection as the influence of intrapsychic factors in the interpretation of external stimuli including interpersonal situations. Personally significant memories, fantasies, wishes, and emotions are often unknowingly activated in many life contexts. Proponents of projective testing believe that standardized tests involving ambiguous stimuli and open-ended responses elicit this content without the test taker's awareness allowing "privileged access" to otherwise well-protected material held at bay by defenses (Wood, Nezworski, Lilienfeld, & Garb, 2003). In his description of the benefits of the Thematic Apperception Test, Henry Murray described unwitting test takers who believed that the ambiguous pictures assessed creativity while not recognizing the psychodynamic significance of their responses: "As a rule, the subject leaves the test happily unaware that he has presented the psychologist with what amounts to an x-ray of his inner self" (Murray, 1943 cited in Lemov, 2011, p. 261).

Projective methods are typically presented as alternatives or complements to objective personality tests with predetermined dichotomous response option (e.g. yes-no; true-false) such as the MMPI or Myers-Briggs Type Indicator. Projective methods such as the Thematic Apperception Test (TAT), Draw-a-Person, and Rorschach instruct participants to generate their own answers with minimal guidance. However, the distinction between objective and

projective assessment may be more apparent than real. As a universal process, projection is not confined to responses to Rorschach or TAT cards but also occurs as response bias or idiosyncratic interpretation of seemingly "objective" cognitive or personality tests. For example, projective scoring methods have been applied to the Wechsler Adult Intelligence Scale (WAIS). On the WAIS Picture Arrangement subtest, patients with borderline personality significantly differed from a non-clinical sample on several dimensions such as "episode integration," reflecting the ability to logically describe interpersonal situations.

Administration and Interpretation of Projective Tasks

However, while responses vary considerably, projective test administration is standardized and has been analogized to an N = 1 experiment. Projective testing is governed by standardized procedures for administration – often including seating arrangements, the wording of instructions as well as a protocol for recording participants' responses.

This standardization ends with test administration. Interpretations of projective data are much more variable ranging from converting verbal narratives to quantitative scores to hermeneutic text interpretation. Historically, projective test data have been viewed as idiographic versus nomothetic with the goal of describing an individual in-depth rather than comparing test responses with pre-existing norms. Personality theorists and researchers differ in their views of the intrapsychic processes activated in projection. The projective process has been described as a visual perceptual mnemonic phenomenon, an unconscious attribution of impulses, wishes, and attitudes through a narrative response to external stimuli, and a symbolic representation of experiences with early caregivers and current intimate relationships.

Projection as a Perpetual-Cognitive Process

Rorschach originally emphasized the perceptual demands of responding to his ink blots – namely the ability to interpret "accidental shapes." Once the percept is registered, the ambiguous stimulus initiates a complex cascade of cognitive processes including a retrospective memory search attempting to locate mnemonic representations of similar visual stimuli which are perceptually integrated. With the activation of mnemonic networks, related semantic and/or visual memories are elicited. As the projective stimulus becomes more ambiguous, personalized reactions and the priming value of the external image are likely to correspondingly increase.

Further support for projection's cognitive demands is found in research in which standardized testing conditions are slightly altered. When the inkblots are administered by someone known to the participant, the number of responses generated is often greater than with a previously unknown examiner. When the instructional set for the Rorschach is changed so that respondents are given the directive to name everything that could be possibly be seen in the blots, the total number of responses may increase three-fold. These data suggest that projection is a complex social cognitive process involving perceptual organization, memory, selection of a response, and verbal explanation.

The principal value of projective tests such as the Rorschach may lie in their assessment of cognitive-perceptual abilities. Within Exner's Comprehensive System, the indices with

strongest support assessed perceptual-cognitive processes rather than measures associated with specific diagnoses or defenses. In clinical samples, the Rorschach Performance Assessment System variables, psychological complexity, assessing the ability to cognitively organize one's environment, and problem solving, demonstrated the strongest associations with measures of psychopathology and neuropsychological functioning.

Projection as Self-Narrative

McAdams (2008) notes that the TAT was a forerunner of the contemporary emphasis on understanding personality through personally constructed, evolving narratives. At the core of personality is a narrative generated to describe life's trajectory. Beginning in early adulthood, this narrative is developed to provide "thematic coherence" including an overarching life direction. While not developing the narrative personality theory to the extent of recent scholars, TAT research suggests that this projective task elicits key aspects of the respondent's life story.

In contrast to impersonal ink blots, Murray believed that familiar visual stimuli evoked a more meaningful and interpretable fund of unconscious material (Miller, 2015). Through stories, individuals unknowingly reveal their attitudes, fears, desires, and views of important relationships (Miller, 2015). Importantly, these accounts have a type of "subjective validity" since interpersonal behavior, ultimately, is interpretive; objectivity is not possible (Miller, 2015).

In developing the TAT with Christiana Morgan, Murray was heavily influenced by classic literature. As a scholar of Herman Melville, Murray analogized the process of telling stories about cards depicting people in ambiguous situations to an "autobiographical novel." Murray believed that "... apperception, was the largely unconscious and inarticulate intrusion of affections and images evoked by objective facts which work by a non-logical inference" (Miller, 2015, p. 17) comparable to a novel.

Projective test data typically acquire meaning through the new story generated through the assessor's interpretation. The fact that two clinicians might interpret the projective narrative differently may be analogous to a medical "second opinion" (Miller, 2015). The richness of projective analysis becomes a product of the triangulation of the participant's story with the narrative provided by two distinct psychological interpretations.

Murray also believed that, depending on the story teller's unconscious conflicts, the process of narrative generation (i.e. how the story is told) also revealed information about cognitive organization, logical reasoning, and emotional regulation (Miller, 2015). Certain pictures would likely have greater power to stimulate personally important unconscious conflicts. Once activated by the stimulus card, the emotion associated with these unrecognized tensions would disrupt the ability to relate a coherent narrative and instead, contribute to tangential, fragmented and illogical stories and at a subtler level, impaired syntax and grammar.

Object Relations and Projection

It is commonly believed that TAT stories provide insight into the subject's view of current important relationships. Object relations theorists emphasize that current relationship behavior is derived from unconscious "working models" of important others developed in

early childhood. Since development of these interpersonal schema begins prior to language acquisition, these internalized models unconsciously influence perceptions of intimate adult relationships. Research over the past two decades supports the concept of adult attachment styles mirroring the secure, anxious, and avoidant styles originally described by Ainsworth and Bell.

From the perspective of projection, these unconscious models and their associated emotions are likely to be activated in interpreting ambiguous stimuli – particularly when human interaction is perceived. To assess these internalized objects, multidimensional scoring systems have been developed for projective tests. Operationalizing object relations projections has contributed to a more detailed definition of these internalized interpersonal representations and their influence on subjective interpretation of relationships: "...the term object relations refers to a congeries of cognitive and affective functions and structures, including ways of representing people and relationships, rules of inference for interpreting the causes of people's feelings, behaviors, interpersonal wishes, [and] conflicts" (Westen, Lohr, Silk, Gold, & Kerber, 1990, p. 355).

The Concept of the Object Scale (CORS) developed by Blatt and colleagues is a multidimensional scoring method applied to Rorschach responses involving humans. After assessing its perceptual accuracy, the response is evaluated on a developmentally based scale including level of attributed motivation, type of action, and whether interactions between human percepts are active or passive. Correlations with psychopathology and other measures of relatedness suggest that the CORS index has construct validity.

A similar quantitative object relations framework has been applied to the TAT. Again, the assumption is that responses to the ambiguous pictures are projections of the subject's internalized multifaceted object representations. Responses are rated on a 5-point scale for complexity of representations of people, emotion attributed to the human characters in the narrative, capacity for investment in others and mutuality of relationships, and appropriate understanding of others' intentions (Westen et al., 1990). Criterion validity for this scoring system is supported by findings that persons with borderline personality disorder score significantly lower on all four TAT dimensions than non-clinical samples and the convergence of these subscales with interview data (Westen et al., 1990).

Projective Assessment: Critiques

Projective methods have been seriously challenged on both conceptual and psychometric grounds. Projective tests have often been found to fall short of acceptable reliability and validity standards associated with objective nomothetic measures. Historically, projective tests have been plagued by fundamental validity problems such as illusory correlations (e.g. drawing a person with an unusually large head indicates concern about one's intelligence). Even Exner's empirically supported Rorschach method has psychometric limitations with only about half of the Comprehensive System's variables demonstrating acceptable interscorer reliability. Some of Exner's diagnostic Rorschach indices demonstrate criterion validity by distinguishing between clinical and non-clinical samples. However, this actuarial method renders the subjectively rich "x-ray of the unconscious" moot by reducing the subject's narrative responses to statistics.

The Future of Projection in Personality

Functional MRI studies have found neurophysiological correlates for suppression, repression, conversion, and dissociation. Recent biopsychological research suggests that projection may be associated with hormones such as testosterone and specific patterns of neural activity. Frontal and parietal brain activation in the context of greater activation of the primary somatosensory cortex was recently found for subjects asked to describe ambiguous visual stimuli. As has been found for other psychodynamic concepts, projection is likely to have an underlying neurocognitive basis – leading to a new definition of this complex process.

Assessing Implicit Motives

Arlin James Benjamin Jr

University of Arkansas – Fort Smith

Examining the assessment of implicit motives involves describing techniques used to assess implicit motives, their reliability, and their validity. One principal type of implicit motives test is the Picture-Story-Exercise, which is derived in part from the Thematic Apperception Test – part of a broader class of projective instruments that presumably enable the scorer to assess individuals' dispositions and needs based upon their reactions to ambiguous stimuli. The second principal type is the Implicit Association Test, which is based on relatively contemporary theories of information processing. In particular, the rationale for this latter test is that much of an individual's attitudes and motives are automatic (i.e. outside of conscious awareness and control) and cannot be measured by standard objective tests.

Picture-Story-Exercise

The assessment of individual differences in implicit motives has its origins in the Thematic Apperception Test (TAT) developed by Murray (1943), and refined by McLelland and colleagues (see, e.g. McClelland, Koestner, & Weinberger, 1989). The Picture-Story-Exercise (PSE) developed by McClelland and colleagues aims to measure motives of which individuals are unaware, such as the need for achievement, affiliation, and power. The PSE utilizes a mixture of approximately eight cards from the original TAT and from other sources (see Lilienfield, Wood, & Garb, 2000 for an overview). Respondents write stories for each picture, and those responses are scored by independent raters for content indicating such motives as achievement, power, and affiliation. The current PSE uses eight cards (e.g. Schultheiss, Liening, & Schad, 2008), and is scored based on respondents' description of the actions of the story characters associated with each picture. Need for power is scored whenever respondents use imagery that indicates forceful actions, or in some way controlling or influencing the emotions of others. Need for achievement is scored whenever respondents use imagery suggesting concern with excellence and performance,

in particular successes and failures. Need for affiliation is scored whenever respondents use imagery associated with maintaining or restoring friendly relations.

The literature on the reliability of the PSE suggests that the instrument shows low internal consistency and test-retest reliability (see Lilienfield et al., 2000). For example, internal consistency typically does not exceed a Cronbach's alpha of .40, and test-retest reliability rarely exceeds .30 (Lilienfield et al., 2000). Inter-rater reliability is generally higher (see e.g. Schultheiss et al., 2008). One proposed alternative measure of reliability is to use ipsative stability, in which the consistency of each individual's profile across stories is measured (Schultheiss et al., 2008). If individual respondents score consistently on need for achievement, power, and affiliation across stories, the PSE can be considered a reliable instrument according to Schultheiss et al. (2008). Preliminary findings suggested that ipsative stability measured sufficiently high relative to other measures of reliability (Schultheiss et al, 2008).

There are also some questions regarding the validity of the PSE. Early research showed low correlations between scores on the PSE and more explicit measures of need for achievement, power, and affiliation (Lilienfield et al., 2000). McLelland and colleagues argued that the lack of correlation was due to each instrument measuring different facets of the constructs in question. Respondents' scores on explicit measures of motives such as achievement are presumed to be driven by short-term concerns and external stimuli, whereas scores on the PSE served as indicators of more long-term motivation and make some statement about predictive validity here (Lilienfield et al., 2000). Correlations with tangible behavioral outcomes such as occupational or school success have generally been around .20, which is not much higher than scores found using equivalent objective measures of need for achievement, power, and affiliation (e.g. Spangler, 1992).

Implicit Association Test

The Implicit Association Test (IAT) was developed approximately two decades ago (Greenwald & Banaji, 1995). The test is administered by presenting respondents with a series of words or pictures on a computer monitor, and instructing respondents to press one key with the left hand if each picture or word corresponds to one decision rule or to press the right hand if the picture or word conforms to another rule. The developers of the IAT argued that respondents would more rapidly press the key for items stereotypically associated with a stereotype for a specific group than they would for items countering the stereotype. In doing so, respondents would be acting outside of conscious awareness or control. A similar approach is used to measure implicit prejudice by having respondents press a key for both positive words and images of faces in one group and pressing another key for both negative words and images of faces in another group. A non-conscious bias toward a group of people may be detected by how quick respondents' reaction times are to negative words and exemplars of the targeted group versus reaction times to positive words and exemplars of the targeted group. Individuals reacting more rapidly to the former pairing are considered to show more non-conscious prejudice (Greenwald, McGhee, & Schwartz, 1998). Versions of the IAT have been used to detect individual differences in implicit prejudice toward African Americans, the elderly, and women, for example.

As with other measures of non-conscious motives, there are concerns regarding the reliability of the IAT. One concern has to do with internal consistency. In general, the internal consistency of the IAT, as measured by Cronbach's alpha, is somewhat low at around .60 (Nosek, Greenwald, & Banaji, 2005). Recall that ideally researchers consider a test reliable when alpha is at .70 or higher. Hence, there appears to be considerable measurement error in the IAT as it is currently designed. The other concern regards the IAT's test-retest reliability. In general, test-retest reliability is low for the IAT, with test-retest indices typically at .60 (Nosek et al., 2005). Respondents who take an IAT more than once may receive noticeably different scores. The correlation between IAT scores at initial testing and IAT scores during subsequent testing is generally lower than considered adequate, suggesting that the IAT is affected by situational cues, and may not be measuring stable individual differences.

Proponents of the IAT contend that the test shows high construct validity. Critics contend that the IAT is more of a measure of cultural knowledge than of respondents' own implicit biases or prejudice. The IAT tends to correlate weakly with other related explicit attitude tests (e.g. Phelps, O'Connor, Cunningham, Funayama, Gatenby, Gore, & Banaji, 2000). Proponents argue that the IAT measures non-conscious attitudes whereas more explicit attitude tests can be influenced by factors such as social desirability, which is similar to the argument made by the developers and proponents of the Picture-Story-Exercise. There is some controversy about the predictive validity of the IAT. Early reports suggested that IAT results consistently predicted relevant behavioral outcomes. Much of the available research focused on the IAT developed to test implicit racial prejudice and discrimination. Initial findings indicated that the IAT appeared to predict discrimination. More recently the predictive validity of the IAT has come into question, with some meta-analytic evidence suggesting that the IAT is a valid predictor of individual variation on various behavioral measures of discrimination (e.g. Greenwald, Banaji, & Nosek, 2015; Greenwald, Poehlman, Uhlmann, & Banaji, 2009) and other meta-analytic evidence suggesting that IAT results do not adequately predict individual variation in discrimination (e.g. Oswald, Mitchell, Blanchard, Jaccard, & Tetlock, 2013).

Conclusions

In summary, although implicit motives tests have been in use for decades and are still generating considerable interest in the psychological literature, there are still questions about the reliability of these tests and their utility in predicting tangible behavioral outcomes.

The Rorschach Test

Sara Bender

Central Washington University

The History of the Rorschach

The Rorschach Inkblot Test is based on the work of Hermann Rorschach. Rorschach was a Swiss-born physician who professionally identified himself primarily as a clinical researcher rather than a clinical practitioner (Ellenberger, 1954). As a young child, Rorschach was said to be intrigued by a popular game called *Klecksographie*, which required players to either make or collect inkblot cards and then make associations and stories based on their collection of those cards. The goal of this game was essentially to develop the most complex plot to explain the design and arrangement of the inkblots accumulated. Rorschach's affection for this game was so great, in fact, that it is said that his nickname actually became "Klec" (Ellenburger, 1954; Rose, Kaser-Boyd, & Maloney, 2001; Schneider, 2001).

As a young adult, Rorschach decided to pursue the study of medicine, completing a psychiatric residency at the Munsterlingen Mental Hospital in Russia between the years of 1909 and 1913 (Pichot, 1984). During this placement, Rorschach became interested in the diagnosis of schizophrenia. It was Rorschach's contention that both functional and dysfunctional perceptual processes were correlated with aspects of the human psyche (Rorschach, 1921; Schwarz, 1996). Given the high prevalence of disordered thoughts and perceptions associated with schizophrenia, Rorschach decided to research how these symptoms reflected on the psyche of those with the diagnosis (Schwarz, 1996).

Perhaps due, in part, to his enchantment with *Klecksographie*, Rorschach maintained a strong interest in the potential for projective tests within a medical environment (Rose et al., 2001). Most notably, he was highly influenced by Carl Jung's Word Association Test. Rorschach's interest in Jung's work is somewhat unsurprising given his fascination with psychoanalysis and the fact that he studied for some time under psychiatrist Eugen Bleuler, Jung's mentor (Pichot, 1984; Rose et al., 2001; Schwarz, 1996). Rorschach believed that projective tests could be leveraged to better understand the psychological profiles associated with various groups of people. He asserted that each group of people would endorse different perceptual patterns leading to a perceptual profile of sorts for that particular

group (Rorschach, 1921; Schwarz, 1996; Searls, 2017). For example, he conducted tests using inkblots to examine the imaginative abilities of more gifted students in comparison to less gifted students. Rorschach suggested that the use of inkblot testing might be useful in better understanding psychosis as well. During his residency at Munsterlingen, he examined the responses given by those with schizophrenia on Jung's Word Association Test and compared those responses with the same individuals' responses to his own inkblot assessment. While the results of each assessment did not perfectly align, he noted a great deal of overlap between the two, suggesting to Rorschach that his method of assessing perceptual processes may be worth pursuing (Rose et al., 2001; Schwarz, 1996)

While the Rorschach test is likely the most famous projective test incorporating a series of inkblots, Hermann Rorschach was certainly not the first researcher to use this technique. There is reference within the literature suggesting that the exploration of ambiguous designs as one way to gain insight into a person's psyche goes as far back as the great Renaissance man, Leonardo da Vinci (Searls, 2017). Kerner conducted the first known formalized examination regarding the use of the inkblot technique, however, in 1857. He indicated that the presentation of ambiguous inkblots could lend insight to an examinee's imagination. Kerner's observations also led to the publication of a text composed of a collection of poems, each inspired by a separate inkblot (Schiller, 1993; Searls, 2017). In 1895, Alfred Binet began using inkblots in his larger efforts to study the nature of intelligence. Like Kerner before him, Binet suggested that inkblots might provide some insight into examinees' imaginative processes (Nicholas, Coubart & Lupart, 2014). Two years later, in 1897, Dearborn (1898) completed a comparable study also examining the potential for inkblots to provide insight to the imagination. Kirkpatrick (1900) later examined the speed with which a person makes associations second to the presentation of an inkblot. Several years later, Whipple (1910) created what is said to be the first standardized set of inkblots used for assessment and research processes. Subsequent studies conducted by Parsons (1917) and Hens (1917) looked at inkblots' insight into the imagination of both children and adults. Collectively, this body of work focused almost exclusively on the content of inkblot descriptions offered by examinees. Little effort was made to interpret the potential meaning of those responses.

It remains uncertain how familiar Rorschach was with most of the efforts mentioned above, if at all. Therefore, it is also unclear if the work of investigators before him influenced Rorschach's efforts pertaining to the inkblot technique. The one known exception to this is that of Szyomon Hens's work (Hens, 1917). Inkblot testing served as the topic of Hens's dissertation. As a part of this project, Hens actually developed and published an inkblot test. Rorschach was aware of Hens's dissertation. Some suggest that Rorschach's knowledge of this work inspired his own focus on this form of assessment (Schwarz, 1996).

Rorschach asserted that there is a strong association between perception and personality. He further theorized that intellectual abilities, emotional style, feelings regarding self and others, and ego functioning all serve as essential aspects of an individual's psychological functioning (Rose et al., 2002; Schwarz, 1996). Owing to this belief, Rorschach differed from his predecessors in that he did not believe that the described content of an inkblot was the most important aspect of understanding a person's personality. Instead, Rorschach suggested that it is the manner in which a person organizes and presents the perceived content of an inkblot into a cohesive response that provides the most insight into his or her cognitive

processes, including those that might be unconscious (Rorschach, 1921). With that, Rorschach attempted to understand what elements of the inkblot affected examinees' responses, including the use of color, the use of shading, form, etc. More simply, Rorschach worked to determine how examinees saw responses and to determine what that perception revealed about the individual's interworkings.

As previously mentioned, Rorschach was motivated to understand differences across groups. As such, he was intentional and methodical in his examination of how groups varied in their perceptions (Schwarz, 1996). His first attempts to develop an inkblot test occurred in his early work with his examinees diagnosed with schizophrenia at the Munsterlingen Mental Hospital (Pichot, 1984). At that time, he compared results of his own assessment with the replies given by the same sample of examinees to Jung's test. As a part of this experience, he experimented with several hundred different inkblots, testing them on a group of 300 examinees with known psychiatric diagnoses and a control group of individuals with no known psychiatric dysfunction. Secondary to the intensive testing of their diagnostic value across groups, Rorschach eventually selected 10 inkblots to serve as the foundation of his test. He conceptualized the set of 10 inkblots as a tool for diagnosis rather than one for deciphering personality. He believed the responses to the inkblots provided by people with different types of mental disorders would reveal patterns or themes associated with designated diagnoses, which could then be categorized, allowing for effective differential diagnoses in future assessments using the inkblots. Rorschach only completed one manuscript, *Psychodiagnostik,* regarding the Rorschach Test, which he published in 1921, only one year before his death in 1922 (Rorschach, 1921; Rose et al., 20002; Schwarz, 1996). His test was translated from German to English in 1942.

Since his death, the Rorschach test's scoring system has been modified several times, first by Beck, then by Klopfler, and others (Rose et al., 2002; Searls, 2017). In 1937, Beck attempted to measure the cognitive perceptual processes involved in examinees' application of meaning to the inkblots. During that same year, Klopfler, on the other hand, aligned his efforts more with those of traditional psychoanalytic inquiry, focusing more on coding the examinees' described content. Over the next three decades, Hertz, Piotrowski, and Rapaport, Gill, and Schafer all developed additional coding systems for the Rorschach. Each of these systems represents an intermediate between the systems developed by Beck and Klopfler (Rose et al., 2002). The variation in coding principles and procedures led to great scrutiny of the Rorschach for some time. Eventually, Exner (1969) completed a meta-analysis of the existing scoring procedures for the Rorschach test in 1967. Through this analysis, he discovered that each of the previously developed coding systems was flawed. Second to this conclusion, Exner and his colleagues developed *The Exner Scoring System*, also known as the *Rorschach Comprehensive System*. This scoring system is supported by a large body of empirical research and is now considered the standard modality for scoring and interpreting Rorschach results (Exner, 1993)

It should also be noted that in 1939, the use of Rorschach Test was expanded in its originally proposed purpose from serving strictly as a diagnostic tool to also act as a projective assessment of personality. Subsequent research and refining efforts have led to standardized administration procedures, the development of a consistent scoring system, special scoring categories, formal empirical studies regarding the efficacy of the Rorschach, as well as the development of a larger normative database from which to compare results

(Rose et al., 2002). Modifications have also led to the inclusion of research control groups for age, gender, intelligence quotient, and socio-economic status (Rose et al., 2002; Searls, 2017; Weiner, 1997).

The Rorschach

Appropriate Use
